Aerogenous inhalation of toxic gases (i.e., ozone, NO<sub>2</sub>), toxic fumes (smoke inhalation), and infection with pneumotropic viruses (influenza, IBR, EVR, canine distemper) are just a few of the different agents that can damage the alveolar epithelium. Hematogenous injury to the vascular endothelium occurs in septicemias (i.e., sepsis), in disseminated intravascular coagulation (DIC), from microembolism, from circulating larva migrans (*Ascaris suum*), from toxins absorbed in the alimentary tract (endotoxin) or toxic metabolites locally generated in the lungs (3 methylindole, paraquat), from release of free radicals in alveolar capillaries (ARDS), and from infections with endotheliotropic viruses (canine adenovirus and classical swine fever [hog cholera]). Damage to the alveolar wall can also occur when inhaled antigens, such as fungal spores, combine with circulating antibodies and form deposits of antigen-antibody complexes (type III hypersensitivity) in the alveolar wall, which initiate a cascade of inflammatory responses and injury (allergic alveolitis). As are interstitial pneumonias in human beings, those of the domestic animals are subdivided, based on some morphologic features, into acute and chronic. It should be kept in mind, however, that not all acute interstitial pneumonias are fatal and that they do not necessarily progress to the chronic form.

Acute interstitial pneumonias begin with injury to either type I pneumonocytes or alveolar capillary endothelium, which provokes a disruption of the blood-air barrier and a subsequent exudation of plasma proteins into the alveolar space. This leakage of proteinaceous fluid into the alveolar lumen constitutes the exudative phase of acute interstitial pneumonia. In some cases of diffuse alveolar damage, exuded plasma proteins mix with lipids and other components of pulmonary surfactant and form elongated membranes that become partially attached to the alveolar and bronchiolar walls. These membranes are referred to as hyaline membranes because they have a hyaline appearance (eosinophilic, homogenous, and amorphous) on microscopic examination (Fig. 9-35). In addition to intraalveolar exudation of fluid, inflammatory edema and neutrophils accumulate in the alveolar interstitium and cause thickening of the alveolar walls. This acute exudative phase is generally followed a few days later by the proliferative phase of acute interstitial pneumonias characterized by hyperplasia of type II pneumonocytes to replace the lost type I alveolar cells. Type II pneumonocytes are, in fact, progenitor cells that differentiate and replace necrotic type I pneumonocytes (see General Aspects of Lung Inflammation). As a consequence, the alveolar walls become increasingly thickened. This process is in part the reason why lungs become rubbery on palpation, what prevents their normal collapse after the thorax is opened, and why the cut surface of the lung has a “meaty appearance.”

Acute interstitial pneumonias are often mild and transient, especially those caused by some respiratory viruses, such as those responsible for equine and porcine influenza. These mild forms of pneumonia are rarely seen in the postmortem room because they are not fatal and do not leave significant sequelae (see Defense Mechanisms of the Exchange System [Alveoli]). In severe cases of acute interstitial pneumonias, animals may die of respiratory failure, usually as a result of diffuse alveolar damage, a profuse exudative phase (leakage of proteinaceous fluid) leading to a fatal pulmonary edema. Examples of this type of fatal acute interstitial pneumonia are bovine pulmonary edema and emphysema, and ARDS in all species.

In contrast to bronchopneumonias, in which distribution of lesions is generally cranioventral, in acute or chronic interstitial pneumonias lesions are more diffusely distributed and generally involve all pulmonary lobes, or in some cases they appear to be more pronounced in the dorsocaudal aspects of the lungs. Three important gross features of interstitial pneumonia are the failure of lungs to collapse when the thoracic cavity is opened, the occasional presence of rib impressions on the lung's pleural surface indicating poor deflation, and the lack of visible exudates in airways unless complicated with secondary bacterial pneumonia (Figs. 9-47, *D* and 9-52). The color of affected lungs varies from diffusely red to diffusely pale gray to a mottled red, pale appearance. Pale lungs are caused by severe obliteration of alveolar capillaries (reduced blood-tissue ratio), especially when there is fibrosis. The texture of lungs with uncomplicated interstitial pneumonia is typically elastic or rubbery, but definitive diagnosis based on texture alone is difficult because of the intrinsic subjectivity of palpation. On a cut surface, the lungs may appear more “meaty” (having the texture and appearance of raw meat) and have no evidence of exudate (Fig. 9-52). It should be remembered, however, that acute interstitial pneumonias, particularly in cattle, are frequently accompanied by pulmonary edema (exudative phase) and interstitial emphysema secondary to partial obstruction of bronchioles by edema fluid and strenuous air gasping before death. Because edema tends to gravitate into the cranioventral portions of the lungs, and emphysema is often more obvious in the dorsocaudal aspects, acute interstitial pneumonias in cattle occasionally have a gross cranioventral-like pattern that may resemble that of bronchopneumonia generally. Lungs are notably heavy because of the edema and the infiltrative and proliferative changes.

514

Fig. 9-52 **Interstitial pneumonia, lung, feeder pig.** **A**, The lung is heavy, pale, and rubbery in texture. It also has prominent costal (rib) imprints (*arrows*), a result of hypercellularity of the interstitium and the failure of the lungs to collapse when the thorax was opened. **B**, Transverse section. The pulmonary parenchyma has a “meaty” appearance and some edema, but no exudate is present in airways or on the pleural surface. This type of lung change in pigs is highly suggestive of a viral pneumonia. (*A and B*, Courtesy Dr. A. López, Atlantic Veterinary College.)

Fig. 9-53 **Interstitial pneumonia, lung, aged ewe.** The alveolar septa are notably thickened by severe interstitial infiltration of lymphocytes and mononuclear cells. H&E stain. (Courtesy Western College of Veterinary Medicine.)

When the source of alveolar injury persists, the proliferative and infiltrative lesions of acute interstitial pneumonia can progress into a different morphologic stage referred to as chronic interstitial pneumonia. The hallmark of chronic interstitial pneumonias is fibrosis of the alveolar walls (with or without intraalveolar fibrosis), and in some cases accumulation of mononuclear inflammatory cells in the interstitium (Fig. 9-53) and persistence of hyperplastic type II pneumonocytes. It should be emphasized again that, although the lesions in interstitial pneumonia are centered in the alveolar walls and its interstitium, a mixture of desquamated epithelial cells, macrophages, and mononuclear cells are usually present in the lumen of bronchioles and alveoli. Other, concurrent changes that can accompany some forms of chronic interstitial pneumonia are formations of microscopic granulomas and hyperplasia of smooth muscle in airways or pulmonary vasculature. Ovine progressive pneumonia, hypersensitivity pneumonitis in cattle and dogs, and silicosis in horses are good veterinary examples of chronic interstitial pneumonia. Pneumoconioses (silicosis, asbestosis), paraquat toxicity, pneumotoxic antineoplastic drugs (bleomycin), and extrinsic allergic alveolitis (farmer's lung) are well-known examples of diseases that lead to chronic interstitial pneumonias in human beings. Massive pulmonary migration of ascaris larvae in pigs also causes interstitial pneumonia (Fig. 9-54).

The term *bronchointerstitial pneumonia* has been introduced into veterinary pathology to describe cases in which pulmonary lesions share some histologic features of both bronchopneumonia and interstitial pneumonia. This combined-type pneumonia is, in fact, frequently seen in many viral infections in which viruses replicate and cause injury in bronchial, bronchiolar, and alveolar cells. Damage to the bronchial and bronchiolar epithelium causes influx of neutrophils similar to that of bronchopneumonias, and damage to alveolar walls causes proliferation of type II pneumonocytes, similar to that which takes place in the proliferative phase of acute interstitial pneumonias. Examples of bronchointerstitial pneumonia include uncomplicated cases of respiratory syncytial virus infections in cattle and lambs, canine distemper, and influenza in pigs and horses.

**Fig. 9-54 Interstitial pneumonia, edema, and hemorrhages, lungs, pig.**

This pig had migrating *Ascaris suum* larvae. The lungs are heavy and wet and failed to collapse when the thorax was opened, due to pulmonary edema. The mottled appearance of lungs is due to the presence of numerous petechiae scattered in the pulmonary parenchyma. Petechiae are likely alveolar hemorrhages caused by migrating larvae. Larvae leave the blood stream to enter the alveoli by penetrating and rupturing alveolar capillaries and thus damage the blood-air barrier in alveolar septa. (Courtesy Dr. J.M. King, College of Veterinary Medicine, Cornell University.)

9.2.3.8.3

### Embolic Pneumonia

516

Embolic pneumonia refers to a particular type of pneumonia in which injury is hematogenous, and the inflammatory response is typically centered in pulmonary arterioles and alveolar capillaries. Lungs act as a biologic filter for circulating particulate matter. Sterile thrombi, unless extremely large, are rapidly dissolved and removed from the pulmonary vasculature by fibrinolysis, causing little if any ill effects. Experimental studies have confirmed that most types of bacteria when injected intravenously (bacteremia) generally are phagocytosed by pulmonary intravascular macrophages, or bypass the lungs and are finally

## Pathologic Basis of Veterinary Disease, 4th Edition

---

trapped in the liver, spleen, joints, or other organs. To cause pulmonary infection, circulating bacteria must first attach to the pulmonary endothelium with specific binding proteins or simply attach to intravascular fibrin and then evade phagocytosis by intravascular macrophages or leukocytes. Infected thrombi because of their size facilitate entrapment of bacteria in the pulmonary vessels and provide a favorable environment to escape phagocytosis. Once trapped in the pulmonary vasculature, usually in small arterioles or alveolar capillaries, offending bacteria disrupt endothelium and basement membranes, spread from the vessels to the interstitium and then to the surrounding lung, forming finally a new nidus of infection.

Embolic pneumonia is characterized by multifocal lesions randomly distributed in all pulmonary lobes because of entrapment of septic emboli (Fig. 9-47, E). Early lesions in embolic pneumonia are characterized grossly by the presence of very small (1 to 10 mm), white foci in the lungs surrounded by a discrete, red, hemorrhagic halo (Fig. 9-55). Unless emboli arrive in massive numbers, causing fatal pulmonary edema, embolic pneumonia is seldom fatal; therefore these acute lesions are rarely seen at postmortem examination. In most instances, acute lesions if unresolved rapidly progress to the formation of pulmonary abscesses that are randomly distributed in all pulmonary lobes and are not restricted to the cranioventral aspects of the lungs, as is the case of abscesses developing from suppurative bronchopneumonia. The early inflammatory lesions in embolic pneumonias are always focal (Fig. 9-56); thus they differ from those of endotoxemia or septicemia, in which endothelial damage and interstitial reactions (interstitial pneumonia) are diffusely distributed in the lungs.

When embolic pneumonia or its sequelae (abscesses) are encountered, careful postmortem evaluation is required to locate the source of septic emboli. Most common causes include rupture of hepatic abscesses into the caudal vena cava in cattle, omphalophlebitis in farm animals, chronic bacterial skin or hoof infections, and infected jugular catheter in all species (Fig. 9-41). Valvular or mural endocarditis in the right side of the heart is also a usual source of septic emboli and embolic pneumonia in all species. Most frequently, bacterial isolates from septic pulmonary emboli in domestic animals are *Arcanobacterium* (*Actinomyces*) *pyogenes*, *Fusobacterium necrophorum*, *Erysipelothrix rhusiopathiae*, *Streptococcus suis* type II, *Staphylococcus aureus*, and *Streptococcus equi*.

516

517

Fig. 9-55 **Embolic pneumonia, lungs, 6-week-old puppy.** Large hemorrhagic foci are scattered relatively uniformly throughout all pulmonary lobes (*arrows*). These hemorrhagic foci are the sites of lodgment of *Pseudomonas aeruginosa* emboli (septic) which originated from necrotizing enteritis. Note the multifocal distribution of the inflammatory foci, which is typical of embolic pneumonia. Septic emboli were also present in the liver. (*Courtesy Atlantic Veterinary College.*)

Fig. 9-56 **Embolic pneumonia, lung, cow.** Foci of necrosis and infiltration of neutrophils (*arrows*) resulting from septic emboli. Note the multifocal distribution of the lesion, which is typical of embolic pneumonia. Vegetative endocarditis involving the tricuspid valve was the source of septic emboli in this cow. H&E stain. (Courtesy Dr. A. López, Atlantic Veterinary College.)

### 9.2.3.8.4

#### Granulomatous Pneumonia

Granulomatous pneumonia refers to a particular type of pneumonia in which aerogenous or hematogenous injury is caused by organisms or particles that cannot be normally eliminated by phagocytosis and that evoke a local inflammatory reaction with numerous alveolar and interstitial macrophages, lymphocytes, a few neutrophils, and sometimes giant cells. The term *granulomatous* is used here to describe an anatomic pattern of pneumonia typically characterized by the presence of pulmonary granulomas.

The pathogenesis of granulomatous pneumonia shares some similarities with that of interstitial and embolic pneumonias. Not surprisingly, some pathologists group granulomatous pneumonias within one of these types of pneumonias (e.g., granulomatous interstitial pneumonia). What makes granulomatous pneumonia a distinctive type is not so much the portal of entry or site of initial injury in the lungs, but the unique type of inflammatory response that results in the formation of granulomas, which can be easily recognized at gross and microscopic examination. The portal of agent entry into lungs can be aerogenous or hematogenous. As a rule, agents causing granulomatous pneumonia are resistant to intracellular killing by phagocytic cells and to the acute inflammatory response and persist in affected tissue for a long time.

The most common causes of granulomatous pneumonia in animals include systemic fungal diseases, such as cryptococcosis (*Cryptococcus neoformans*), coccidioidomycosis (*Coccidioides immitis*), histoplasmosis (*Histoplasma capsulatum*), and blastomycosis (*Blastomyces dermatitidis*). In most of these fungal

## Pathologic Basis of Veterinary Disease, 4th Edition

---

diseases, the port of entry is aerogenous and from the lungs the fungi disseminate systemically to other organs, particularly the lymph nodes, liver, and spleen. Granulomatous pneumonia is also caused by some bacterial diseases, such as tuberculosis (*Mycobacterium bovis*) in all species, and inhaled foreign material (starch). Sporadically, aberrant parasites such as *Fasciola hepatica* in cattle and aspiration of foreign bodies can also cause granulomatous pneumonia. Feline infectious peritonitis is one of a few viral infections of domestic animals that result in granulomatous pneumonia. Lesions are caused by the deposition of antigen-antibody complexes in the vasculature of many organs, including the lungs, and subsequent vasculitis.

Granulomatous pneumonia is characterized by the presence of variable numbers of caseous or noncaseous granulomas randomly distributed in the lungs (Figs. 9-47, F and 9-57). On palpation, lungs have a typical nodular character given by well-circumscribed, variably sized nodules that, generally, have a firm texture, especially if calcification has occurred. During postmortem examination, granulomas in the lungs occasionally can be mistaken for neoplasms. Microscopically, pulmonary granulomas are composed of a center of necrotic tissue, surrounded by a rim of macrophages (epithelioid cells) and giant cells and an outer delineated layer of connective tissue commonly infiltrated by lymphocytes and plasma cells (Fig. 9-58). Unlike other types of pneumonias, the causative agent in granulomatous pneumonia can, in many cases, be identified microscopically in sections stained by PAS reaction or by Grocott-Gomori's methenamine silver (G-GMS) stains for fungi or the acid-fast stain for mycobacteria.

### 9.2.3.9 SPECIES-SPECIFIC PNEUMONIAS

#### 9.2.3.9.1 Pneumonias of Horses

Viral infections of the respiratory tract, particularly equine viral rhinopneumonitis and equine influenza, are important diseases of horses around the world. The effects of these and other respiratory viruses on the horse can be manifested in three distinct ways. First, as pure viral infections, their severity may range from mild to severe, making them a frequent interfering factor in training and athletic performance. Second, superimposed infections by opportunistic bacteria such as *Streptococcus* spp., *Escherichia coli*, *Klebsiella pneumoniae*, *Rhodococcus equi*, and various anaerobes can cause fibrinous or suppurative bronchopneumonias. Third, it is possible, but yet unproven, that viral infections may also predispose horses to “airway hyperresponsiveness” and “chronic obstructive pulmonary disease.”

517  
518

Fig. 9-57 **Pulmonary tuberculosis, lung, aged cow.** **A**, Multifocal, coalescing granulomatous pneumonia involves most of the lung, except for the dorsal portion of the caudal lung lobe. **B**, Transverse section. Large multifocal to confluent caseating granulomas are present in the pulmonary parenchyma. 9.2.3.9.1.1

### Equine influenza

Equine influenza is an important and highly contagious flulike respiratory disease of horses characterized by high morbidity and low mortality, and explosive outbreaks occur in susceptible populations of horses. Two antigenically unrelated subtypes of equine influenza viruses have been identified (A/equi-1 and A/equi-2). The course of the disease is generally mild and transient, and its importance is primarily because of its economic impact on horse racing. The types of injury and host response in the conducting system are described under Specific Diseases of Nasal Cavity and Sinuses (see Equine Nasal Diseases). Uncomplicated lesions in the lungs are those of mild and self-limiting bronchointerstitial pneumonia. The influenza virus antigen can be readily demonstrated in ciliated cells and alveolar macrophages. Clinical signs are characterized by fever, cough, abnormal lung sounds (crackles and wheezes), anorexia, and depression. Secondary bacterial infections (*Streptococcus equi*, *Streptococcus zooepidemicus*, *Streptococcus aureus*) commonly complicate equine influenza.

9.2.3.9.1.2

### Equine viral rhinopneumonitis (EVR, equine herpesvirus infection)

This respiratory disease of young horses is particularly important in weanlings between 4 and 8 months of age and to a much lesser extent in young foals and adult horses. The causative agent is a ubiquitous equine herpesvirus (EHV-1 and EHV-4) that, in addition to respiratory disease, can cause abortion in pregnant mares and neurologic diseases in horses of all ages (see also EVR under Equine Nasal Diseases).

518

The respiratory form of EVR is a mild and a transient bronchointerstitial pneumonia seen only by pathologists when complications with secondary bacterial infections cause a fatal bronchopneumonia (*Streptococcus equi*, *Streptococcus zooepidemicus*, *Staphylococcus aureus*). Uncomplicated lesions in EVR are seen only in aborted fetuses or in foals that die within the first few days of life. They consist of focal areas of necrosis (0.5 to 2 mm) in various organs, including liver, adrenal glands, and lungs. In some cases intranuclear inclusion bodies are microscopically observed in these organs. Recent outbreaks of interstitial pneumonia in donkeys have been attributed to novel strains of equine (asinine) herpesvirus. Clinically, horses affected with the respiratory form of EVR exhibit fever, anorexia, conjunctivitis, cough, and nasal discharge.

519

9.2.3.9.1.3

### Equine viral arteritis (EVA)

This pansystemic disease of foals and horses, caused by an arterivirus, occurs sporadically throughout the world, sometimes as an outbreak. This virus infects and causes severe cellular injury in macrophages and endothelial cells. Gross lesions consist of hemorrhage and edema in many tissues, including pulmonary edema, voluminous hydrothorax and hydroperitoneum, and edematous distention of the intestinal walls, scrotum, and periorbital tissues. Fibrinoid necrosis and inflammation of the vessel walls (vasculitis), particularly the small muscular arteries (lymphocytic arteritis), are the underlying microscopic lesions that explain most of the clinical and pathologic features. Pulmonary lesions are those of interstitial pneumonia with hyperplasia of type II pneumocytes and vasculitis with distended pulmonary lymphatic vessels and abundant fluid in the bronchoalveolar spaces. Viral antigen can be detected by immunoperoxidase techniques in the walls and endothelial cells of affected pulmonary vessels and in alveolar macrophages.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Clinical signs are respiratory distress, fever, abortion, diarrhea, colic, and edema of the limbs and ventral abdomen. Respiratory signs are frequently seen and consist of serous or mucopurulent rhinitis and conjunctivitis with palpebral edema. Like most viral respiratory infections, EVA can predispose horses to opportunistic secondary bacterial pneumonias.

### 9.2.3.9.1.4

#### African horse sickness

This vector-borne disease of horses, mules, and donkeys is caused by an orbivirus (family Reoviridae) and is characterized by respiratory distress or cardiovascular failure. It has a high mortality rate—up to 95% in the native population of horses in Africa, the Middle East, India, Pakistan, and most recently Spain. Although the virus is transmitted primarily by insects (*Culicoides*) to horses, other animals such as dogs can be infected by eating infected equine flesh. The pathogenesis of African horse sickness remains unclear, but this equine orbivirus has an obvious tropism for pulmonary and cardiac endothelial cells, and to a lesser extent mononuclear cells. Based on clinical signs (not pathogenesis), African horse sickness is arbitrarily divided into four different forms—namely pulmonary, cardiac, mixed, and mild.

The pulmonary form is characterized by severe respiratory distress and rapid death because of massive pulmonary edema, presumably from viral injury to the pulmonary endothelial cells. Grossly, large amounts of froth are present in the airways, lungs fail to collapse, subpleural lymph vessels are distended, and the ventral parts of the lungs are notably edematous. In the cardiac form, recurrent fever is detected, and heart failure results in subcutaneous and interfascial edema, most notably in the neck and supraorbital region. The mixed form is a combination of the respiratory and cardiac forms. Finally, the mild form, rarely seen in postmortem rooms, is characterized by fever and clinical signs resembling those of equine influenza; it is, in most cases, transient and followed by a complete recovery. This mild form is most frequently seen in donkeys, mules, and zebras and in horses with some degree of immunity. Detection of viral antigen for diagnostic purposes could be done by immunohistochemistry in paraffin-embedded tissues.

### 9.2.3.9.1.5

#### Equine *Morbillivirus* (Hendra virus)

Fatal cases of a novel respiratory disease in horses and human beings suddenly appeared around 1994 in Hendra, a suburb of Brisbane, Australia. This outbreak was attributed to a newly recognized virus that was tentatively classified as equine *Morbillivirus* and is currently referred to as Hendra virus, a new member of the subfamily Paramyxoviridae. The involvement of fruit bats (flying foxes) in the transmission of this viral disease has been suggested. The lungs of affected horses are severely edematous with gelatinous distention of pleura and subpleural lymph vessels. Microscopically the lungs have diffuse alveolar edema associated with vasculitis, capillary thrombosis, distention of lymphatic vessels, and presence of multinucleated syncytial cells typical of *Morbillivirus* infections in the endothelium of small pulmonary blood vessels and alveolar capillaries. The characteristic inclusion bodies seen in other *Morbillivirus* infections are not seen in horses; however, the virus can be easily detected by immunohistochemistry in pulmonary endothelial cells and alveolar epithelial cells. Clinical signs are nonspecific and include fever, anorexia, respiratory distress, and nasal discharge.

*Rhodococcus equi*, formerly known as *Corynebacterium equi*, is an important cause of morbidity and mortality in foals around the world. It is a facultative intracellular gram-positive bacterium that causes two major forms of disease—one involves the intestine, causing ulcerative enterocolitis, and the other affects the respiratory tract, resulting in a severe and often fatal bronchopneumonia. Although half of foals with pneumonia have ulcerative enterocolitis, it is rare to find animals with intestinal lesions alone. Occasionally, infection is disseminated to lymph nodes, joints, bones, genital tract, and other organs. Because *Rhodococcus equi* is present in soil and feces of herbivores (particularly foals), it is not unusual for the disease to become enzootic on farms where the organism has been shed earlier by infected foals. Serologic evidence of infection in horses is widespread, yet clinical disease is sporadic and largely restricted to young foals or to adult horses with severe immunosuppression. Virulence factors encoded by plasmids (virulence-associated proteins) appear to be responsible for the survival of *Rhodococcus equi* in macrophages, thus determining the evolution of the disease. This bacterium also has been sporadically incriminated with infections in cattle, goats, pigs, dogs, and cats, and quite often in immunocompromised human beings—for example, those infected with the AIDS virus, after organ transplantation, or undergoing chemotherapy.

519

520

It is still debatable whether natural infection starts as a bronchopneumonia (aerogenous route) from which *Rhodococcus equi* reaches the intestine via swallowed sputum, or whether infection starts as an enteritis (oral route) with subsequent bacteremia into the lungs. The results of experimental studies suggest that natural infection with this organism likely starts from inhalation of infected dust or aerosols. Once in the lung, *Rhodococcus equi* undergoes rapid phagocytosis by alveolar macrophages, but because of defective phagosome-lysosome fusion and premature lysosomal degranulation, bacteria survive and multiply, eventually leading to the destruction of the macrophage. Interestingly, *Rhodococcus equi* appears to be easily killed by neutrophils but not macrophages. Released cytokines and lysosomal enzymes and bacterial toxins are responsible for extensive caseous necrosis of the lungs and the recruitment of large numbers of neutrophils, macrophages, and giant cells containing intracellular gram-positive organisms in their cytoplasm.

Depending on the stage of infection and the immune status and age of affected horses, pulmonary lesions induced by *Rhodococcus equi* can vary from suppurative bronchopneumonia to granulomatous pneumonia with caseated necrosis. In young foals, the infection starts as a suppurative cranioventral bronchopneumonia, which progresses within a few days into small variable-size pulmonary abscesses. These abscesses rapidly transform into pyogranulomatous nodules some of which become confluent and form large masses of caseous exudate (Fig. 9-59). Microscopically the early lesion starts with neutrophilic infiltration, followed by an intense influx of alveolar macrophages into the bronchoalveolar spaces. This type of histiocytic inflammation tends to persist for a long period of time because *Rhodococcus equi* is a facultative intracellular organism that survives the bactericidal effects of equine alveolar macrophages. In the most chronic cases, the pulmonary lesions culminate with the formation of large necrotic masses with extensive fibrosis of the surrounding pulmonary parenchyma. PCR analysis of tracheal aspirates has successfully been used as an alternative to bacteriologic culture in the diagnosis of *Rhodococcus equi* infection in live foals.

Clinically, *Rhodococcus equi* infection can be acute, with rapid death caused by severe bronchopneumonia, or chronic, with depression, cough, weight loss, and respiratory distress. In either form, there may be diarrhea, arthritis, or subcutaneous abscess formation.

9.2.3.9.1.7

### Other pneumonias of horses

*Chlamydophila (Chlamydia) psittaci*, an obligatory intracellular pathogen, can cause systemic infection in many mammalian and avian species; in horses, it also causes keratoconjunctivitis, rhinitis, pneumonia, abortion, polyarthritis, enteritis, hepatitis, and encephalitis. Serologic studies suggest that infection without apparent disease is common in horses. Horses experimentally infected with *Chlamydophila psittaci* develop mild and transient bronchointerstitial pneumonia. Detection of chlamydial organisms in affected tissue is not easy and requires special laboratory techniques, such as PCR and fluorescent antibody tests.

Horses are susceptible to mycobacteriosis (*Mycobacterium avium* complex, *Mycobacterium tuberculosis*, and *Mycobacterium bovis*). The intestinal tract and associated lymph nodes are usually affected, suggesting ingestion, but with hematogenous dissemination, the lungs are involved (Fig. 9-60). The tubercles (granulomas) definitely differ from those in ruminants and pigs, being smooth, gray, solid nodules without grossly visible caseous necrosis or calcification; they typically appear more like sarcomas. Microscopically, the tubercles are composed of macrophages, epithelioid cells, and multinucleated giant cells. Fibrosis increases with time, accounting in part for the sarcomatous appearance.

Adenovirus infections occur commonly in Arabian foals with combined immunodeficiency (CID), a hereditary lack of B and T lymphocytes. In cases of adenoviral infection, large basophilic or amphophilic inclusions are present in the nuclei of tracheal, bronchial, bronchiolar, alveolar, renal, and intestinal epithelial cells. As it occurs in other species, infection with a unique fungal pathogen known as *Pneumocystis carinii* typically occurs in immunosuppressed or immunoincompetent individuals, such as Arabian foals with CID. Diagnosis of *Pneumocystis carinii* requires microscopic examination of lungs and special stains (see under Pneumonias of Pigs).

520

521

Fig. 9-59 **Granulomatous pneumonia (*Rhodococcus equi*), lungs, foal.**

**A**, Cranioventral consolidation of the lungs with subpleural granulomas. Note that the pneumonic lesions in this foal are unilateral. This was an experimental case in which a foal was intratracheally inoculated with a suspension of *Rhodococcus equi*. **B**, Cut surface. Note the large, confluent, caseated granulomas. (**A and B**, Courtesy Drs. J. Yager and J. Prescott, Ontario Veterinary College.)

Fig. 9-60 **Multifocal granulomatous pneumonia, tuberculosis (*Mycobacterium avium-intracellulare*), lung, cut surface, aged horse.** Note the large numbers of noncaseating granulomas scattered throughout the pulmonary parenchyma. In horses, tuberculous granulomas often resemble sarcomatous nodules. (Courtesy Western College of Veterinary Medicine.)

Diffuse proliferative interstitial pneumonias of undetermined cause that can progress to pulmonary fibrosis have been reported in North American horses. The gross and microscopic lesions are reminiscent of those of bovine pulmonary edema and emphysema with hyperplasia of type II pneumonocytes. The cause of this form of equine interstitial pneumonia is not known, but toxic and viral causes have been proposed.

Aspiration pneumonia is often a devastating sequela to improper gastric tubing of horses, particularly exogenous lipid pneumonia from mineral oil delivered into the trachea in treatment of colic. Gross and microscopic lesions are described in detail in the section Aspiration Pneumonias of Cattle.

521

9.2.3.9.1.7.1

### Parasitic pneumonias of horses.

522

*Parascaris equorum* is a large nematode (roundworm) of the small intestine of horses; the larval stages migrate through the lungs as ascarid larvae do in pigs. It is still unclear whether migration of *Parascaris equorum* larvae can cause significant pulmonary lesions under natural conditions. Experimentally, migration of larvae results in coughing, anorexia, weight loss, and small necrotic foci and petechial hemorrhages in the liver, hepatic and tracheobronchial lymph nodes, and lungs. Microscopically, eosinophils are prominent in the interstitium and airway mucosa during the parasitic migration and in focal granulomas caused by dead larvae in the lung.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

*Dictyocaulus arnfieldi* is not a very pathogenic nematode, but it should be considered if there are signs of coughing in horses that are pastured together with donkeys. Donkeys are considered the natural hosts and can tolerate large numbers of parasites without ill effects. *Dictyocaulus arnfieldi* does not usually become patent in horses, so examination of fecal samples is not useful; bronchoalveolar lavage (BAL) is only occasionally diagnostic because eosinophils, but not parasites, are typically found in the lavage fluid. Mature parasites (up to 8 cm in length) cause obstructive bronchitis, edema, and atelectasis particularly along the dorsocaudal lung. The microscopic lesion is an eosinophilic bronchitis similar to the less acute infestations seen in cattle and sheep with their *Dictyocaulus* species.

9.2.3.9.2

### Pneumonias of Cattle

9.2.3.9.2.1

#### Bovine respiratory disease (BRD) complex; acute undifferentiated respiratory disease

These two general terms are often used by clinicians to describe acute and severe bovine respiratory illness of clinically undetermined cause. The BRD complex and acute undifferentiated respiratory disease are clinical terms that do not imply any particular type of pneumonia and therefore should not be used in pathology reports. Clinically, the BRD complex includes enzootic pneumonia of calves (multifactorial etiology); pneumonic mannheimiosis (*Mannheimia haemolytica*); respiratory histophilosis (*Histophilus somni*), previously known as respiratory hemophilosis (*Haemophilus somnus*); respiratory viral infections such as infectious bovine rhinotracheitis (IBR/BHV-1), parainfluenza-3 (PI-3 virus), and bovine respiratory syncytial virus (BRSV); and noninfectious interstitial pneumonias such as bovine pulmonary edema and emphysema, reinfection syndrome, and many others.

Enzootic pneumonia, sometimes simply referred to as “calf pneumonia,” is a disease caused by a variety of etiologic agents that produces an assortment of lung lesions in young, intensively housed calves. Morbidity is often high (up to 90%), but fatalities are uncommon (>5%) unless management is poor or unless new, virulent pathogens are introduced by additions to the herd.

9.2.3.9.2.2

#### Bovine enzootic pneumonia

Enzootic pneumonia is also called viral pneumonia because it often begins with an acute respiratory infection with PI-3 virus, BRSV, or possibly with one or more of several other viruses (adenoviruses, BHV-1, reoviruses, and rhinoviruses). Mycoplasmas, notably *Mycoplasma dispar*, *Mycoplasma bovis*, *Ureaplasma*, and possibly *Chlamydophila* may also be primary agents. Following infection with any of these agents, opportunistic bacteria such as *Pasteurella multocida*, *Arcanobacterium* (*Actinomyces*) *pyogenes*, *Histophilus somni*, *Mannheimia haemolytica*, and *Escherichia coli* cause a secondary suppurative bronchopneumonia, the most serious stage of enzootic pneumonia. The pathogenesis of the primary invasion and how it predisposes the host to invasion by the opportunists are poorly understood, but it is likely that there is impairment of pulmonary defense mechanisms. Environmental factors, including air quality (poor ventilation), high relative humidity, and animal crowding have been strongly incriminated. The immune status of the calf also plays an important role in the development and severity of enzootic pneumonia. Calves with bovine leukocyte adhesion deficiency (BLAD), which prevents the migration of neutrophils from the capillaries, are highly susceptible to bronchopneumonia.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Lesions are variable and depend largely on the agents involved and on the duration of the inflammatory process. In the acute phases, lesions caused by viruses are those of bronchointerstitial pneumonia, which are generally mild and transient, and therefore are seen only sporadically at necropsy. Microscopically the lesions are necrotizing bronchiolitis, necrosis of type I pneumonocytes with hyperplasia of type II pneumonocytes, and mild interstitial and alveolar edema.

In the case of PI-3 and BRSV infection, intracytoplasmic inclusion bodies and the formation of large multinucleated syncytia, resulting from the fusion of infected bronchiolar epithelial cells, can also be observed in the lungs (Fig. 9-61).

The mycoplasmas also can cause bronchiolitis, bronchiolar and alveolar necrosis, and an interstitial reaction, but in contrast to viral-induced pneumonias, mycoplasmal lesions tend to progress to a chronic stage characterized by striking peribronchiolar lymphoid hyperplasia (cuffing pneumonia). When complicated by secondary bacterial infections (e.g., *Pasteurella multocida*, *Arcanobacterium pyogenes*), viral or mycoplasmal lesions change from a pure bronchointerstitial to a suppurative bronchopneumonia (Fig. 9-62). In late stages of bronchopneumonia, the lungs contain a creamy-mucoid exudate in the airways and often have pulmonary abscesses or bronchiectasis (Fig. 9-46). Airway hyperreactivity has been recently described in neonatal calves following BRSV infection; however, the significance of this syndrome in relation to enzootic pneumonia of calves is still under investigation.

522

523

It should be noted that the same viruses and mycoplasmas involved in the enzootic pneumonia complex can also predispose cattle to other diseases, such as pneumonic mannheimiosis (*Mannheimia haemolytica*). Clinically, enzootic pneumonia is usually mild, but fatal cases are occasionally seen even in farms with optimal health management.

Fig. 9-61 **Necrotizing bronchiolitis, bovine respiratory syncytial virus, lung, 5-week-old calf.** This is the reparative stage of necrotizing bronchiolitis and is characterized by epithelial hyperplasia and exfoliation of necrotic cells into the bronchiolar lumen. Epithelial cells are swollen, and the cytoplasm of some cells contains eosinophilic inclusion bodies surrounded by a clear halo (*arrows*). Many of these hyperplastic bronchiolar cells eventually undergo apoptosis during the last stage of bronchiolar repair. H&E stain. (*Courtesy Dr. A. López, Atlantic Veterinary College.*)

Fig. 9-62 **Suppurative bronchopneumonia, right lung, calf.** **A,** Approximately 40% of the lung parenchyma is consolidated and includes most of the cranial lung lobe and the ventral portions of the middle and caudal lung lobes, a distribution often designated as cranioventral. Note the dark color of the consolidated lung and the normal appearance of the dorsal portion of the caudal lung lobe. **B,** Transverse section of the cranial lung lobe showing bronchi filled with purulent exudate. ### 9.2.3.9.2.3

#### Pneumonic mannheimiosis (shipping fever)

Shipping fever (transit fever) is a vague clinical term used to denote acute respiratory diseases that occurred in cattle several days or weeks after shipment. The disease is characterized by a severe fibrinous bronchopneumonia, reflecting the fact that death generally occurs early or at an acute stage. Because *Mannheimia haemolytica* (formerly *Pasteurella haemolytica*) is typically isolated from affected lungs, the names pneumonic mannheimiosis and pneumonic pasteurellosis have been used synonymously. It is known that pneumonic mannheimiosis can occur in animals that have not been shipped and that organisms other than *Mannheimia haemolytica* can cause similar lesions. Therefore, the term *shipping fever* should be relinquished in favor of more specific names such as pneumonic mannheimiosis or respiratory histophilosis (hemophilosis).

Pneumonic mannheimiosis (shipping fever) is the most important respiratory disease of cattle in North America, particularly in feedlot animals that have been through the stressful marketing and assembly processes. *Mannheimia haemolytica* biotype A, serotype 1 is the etiologic agent responsible for the severe pulmonary lesions. A few investigators still consider that *Pasteurella multocida* and other serotypes of *Mannheimia haemolytica* are also causes of this disease.

Even after many years of intense investigation, from the gross lesions to the molecular aspects of the disease, the pathogenesis of pneumonic mannheimiosis remains incompletely understood. Experiments have established that *Mannheimia haemolytica* A1 alone is usually incapable of causing disease

523

524

## Pathologic Basis of Veterinary Disease, 4th Edition

---

because it is rapidly cleared by pulmonary defense mechanisms. These findings may explain why *Mannheimia haemolytica*, in spite of being present in the nasal cavity of healthy animals, only sporadically causes disease. For *Mannheimia haemolytica* to be established as a pulmonary infection, it is first required that stressors impair the defense mechanisms and allow the bacteria to colonize the lung (see Impairment of Defense Mechanisms). These stressors include weaning, transport, fatigue, crowding, mixing of cattle from various sources, inclement weather, temporary starvation, and viral infections. Horizontal transmission of viruses and *Mannheimia haemolytica* occurs during crowding and transportation of cattle.

Viruses that most commonly predispose cattle to pneumonic manheimiosis include BHV-1, PI-3, BRSV, and several others. Once established in the lungs, *Mannheimia haemolytica* causes lesions by means of different virulence factors, which include endotoxin, lipopolysaccharide, and outer membrane proteins, but the most important is probably the production of a leukotoxin (exotoxin), which binds and kills bovine macrophages and neutrophils. The fact that this toxin exclusively affects ruminant leukocytes probably explains why *Mannheimia haemolytica* is a respiratory pathogen in cattle and sheep but not in other species. During *Mannheimia haemolytica* infection, alveolar macrophages, neutrophils, and mast cells release maximum amounts of proinflammatory cytokines, particularly TNF- $\alpha$ , IL-1, IL-8, adhesion molecules, histamine, and leukotrienes. By locally releasing enzymes and free radicals, leukocytes further contribute to the injury and necrosis of bronchiolar and alveolar cells.

The gross lesions of acute and subacute pneumonic manheimiosis are the prototype of fibrinous (lobar) bronchopneumonia, with prominent fibrinous pleuritis ([Fig. 9-63](#)) and pleural effusion. Lesions are always cranioventral and usually ventral to a horizontal line through the tracheal bifurcation. The interlobular septa are distended by yellow, gelatinous edema and fibrin. The “marbling” of lobules is the result of areas of coagulation necrosis, interlobular interstitial edema, and congestion ([Fig. 9-64](#)). The necrotic areas are typically bordered by a rim of elongated cells often referred to as “swirling macrophages” or “oat-shaped cells,” now known to be degenerating neutrophils mixed with a few alveolar macrophages. Edema and fibrin are the major components of the exudate in alveoli and interlobular septa ([Fig. 9-64](#)). The extensive deposition of fibrin is the result of increased permeability of alveolar capillaries exacerbated by altered platelet function, increased procoagulant activity, and diminished profibrinolytic activity in the lungs. The trachea and bronchi can have considerable amounts of blood and exudate transported by the mucociliary escalator or coughed up from deep within the lungs, but their walls are not particularly involved. Because of the necrotizing process, sequelae to pneumonic manheimiosis can be serious and can include abscesses, sequestra (isolated piece of necrotic lung), chronic pleuritis, fibrous pleural adhesions, and bronchiectasis.

**Fig. 9-63 Fibrinous bronchopneumonia (pleuropneumonia), pneumonic manheimiosis (*Mannheimia haemolytica*), right lung, steer.** Note the cranioventral pneumonia involving approximately 85% of the lung parenchyma. The lung is firm and swollen, and the pleura is covered with a thick layer of fibrin. (Courtesy College of Veterinary Medicine, University of Illinois.)

Clinically, pneumonic manheimiosis is characterized by a severe toxemia that can kill animals even when considerable parts of the lungs remain functional and structurally normal. Cattle usually become depressed, febrile (104° to 106° F/40° to 41° C), and anorexic and have a productive cough, encrusted nose, mucopurulent nasal exudate, shallow respiration, or an expiratory grunt.

### 9.2.3.9.2.4

#### Hemorrhagic septicemia

Pneumonic manheimiosis should not be confused with hemorrhagic septicemia (septicemic pasteurellosis) of ruminants caused by inhalation or ingestion of serotypes B and E of *Pasteurella multocida*. This disease does not occur in North America and currently is reported only from some countries in Asia and Africa. In contrast to pneumonic manheimiosis, in which lesions are always confined to the lower respiratory tract, the bacteria in hemorrhagic septicemia always disseminates hematogenously to other organs. Hemorrhagic septicemia is clinically characterized by a severe, acute septicemia, high fever, and rapid death. At necropsy, typically, generalized petechiae are present on the serosal surfaces of the intestine, heart, lungs, and in skeletal muscles. Superficial and visceral lymph nodes are swollen and hemorrhagic. Variable lesions include edematous and hemorrhagic lungs with or without consolidation, hemorrhagic enteritis, blood-tinged fluid in the thorax and abdomen, and subcutaneous edema of the head, neck, and ventral abdomen. Bacteria can be cultured from blood and tissue.

524

525

Fig. 9-64 **Pneumonic manheimiosis (*Mannheimia haemolytica*), lung, steer.** **A**, Cut surface. Interlobular septa (*arrowheads*) are notably distended by edema and fibrin. In the lung parenchyma are irregular areas of coagulative necrosis (*arrows*) surrounded by a rim of inflammatory cells. **B**, Note a large area of necrosis (*N*) of the pulmonary parenchyma. Typically these necrotic areas are surrounded by an outer dense layer of inflammatory cells. Alveoli in the bottom right corner are edematous; those in the top left corner are relatively normal. H&E stain. **C**, Note alveoli filled with fibrin (*center*) and with neutrophils and macrophages (*top right*). H&E stain. **D**, *Mannheimia haemolytica* produces leukotoxin (cytotoxic for ruminant leukocytes) and lipopolysaccharide. Note the accumulation of cells, chiefly neutrophils, in the alveoli. Also note the active hyperemia of acute inflammation of the alveolar capillaries. H&E stain. (**A**, Courtesy Dr. A. López, Atlantic Veterinary College. **B**, **C**, and **D**, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

9.2.3.9.2.5

### Respiratory histophilosis (hemophilosis)

Respiratory hemophilosis is part of the *Histophilus somni* (*Haemophilus somnus*) disease complex, which has different clinicopathologic forms, each one involving different organs. This complex includes septicemia, encephalitis (known as thrombotic meningoencephalitis [TME]), pneumonia

## Pathologic Basis of Veterinary Disease, 4th Edition

(respiratory histophilosis [hemophilosis]), pleuritis, myocarditis, arthritis, ophthalmitis, conjunctivitis, otitis, and abortion. The portals of entry for the different forms of histophilosis have not been properly established.

The respiratory form of bovine histophilosis is the result of the bacterium's capacity to produce both suppurative and fibrinous bronchopneumonia. The latter is in some cases indistinguishable from that of pneumonic manheimiosis. The pathogenesis of respiratory histophilosis is still poorly understood, and the disease cannot be reproduced consistently by administration of *Histophilus somni* alone. Like *Mannheimia haemolytica*, it requires predisposing factors, such as stress or a preceding viral infection. *Histophilus somni* is often isolated from the lungs of calves with enzootic pneumonia. The capacity of *Histophilus somni* to cause septicemia and localized infections in the lungs, brain, eyes, ear, heart, mammary gland, male and female genital organs, or placenta is perhaps attributable to specific virulence factors, such as immunoglobulin binding proteins (IgBPs). Also, *Histophilus somni* has the ability to undergo structural and antigenic variation, evade phagocytosis by promoting leukocytic apoptosis, inhibit intracellular killing, reduce transferrin concentrations, and induce endothelial apoptosis in affected calves. Mixed pulmonary infections of *Histophilus somni*, *Mannheimia haemolytica*, *Pasteurella multocida*, and mycoplasmas are fairly common in calves.

### 9.2.3.9.2.6

#### Contagious bovine pleuropneumonia

Contagious bovine pleuropneumonia is of historical interest in veterinary medicine, as the object of early national control programs for infectious disease. It was eradicated from North America in 1892 and from Australia in the 1970s, but it is still enzootic in large areas of Africa, Asia, and Eastern Europe. The etiologic agent, *Mycoplasma mycoides* ssp. *mycoides* small colony type, was the first *Mycoplasma* isolated and is one of the most pathogenic of those that infect domestic animals. Portal of entry is aerogenous, and infections occur when a susceptible animal inhales infected droplets. The pathogenic mechanisms are still inadequately understood but are suspected to involve toxin production, unregulated production of TNF- $\alpha$ , ciliary dysfunction, immunosuppression, and immune-mediated vasculitis. Vasculitis and thrombosis of blood vessels lead to lobular infarction.

The name of the disease is a good indication of the gross lesions. It is a severe, fibrinous bronchopneumonia (pleuropneumonia) similar to that of pneumonic manheimiosis but having a more pronounced "marbling" of the lobules because of extensive lymphatic thrombosis and interlobular edema (different stages of inflammation), 60% to 79% of lesions in the caudal lobes (not cranioventrally), and more frequent and larger pulmonary sequestra (necrotic lung encapsulated by connective tissue). Microscopically the appearance again is like that of pneumonic manheimiosis, except that vasculitis and thrombosis of pulmonary arterioles and capillaries are much more obvious and are clearly the major cause of the infarction and thrombosis of lymphatic vessels in interlobular septa. *Mycoplasma mycoides* ssp. *mycoides* small colony type remains viable in the sequestra for many years, and under stress (e.g., starvation), the fibrous capsule may break down, and the mycoplasma are released into the airways and become a source of infection for other animals. Vaccination is highly effective in preventing the disease.

### 9.2.3.9.2.7

#### Bovine tuberculosis

Tuberculosis is an ancient, communicable, worldwide, chronic disease of human beings and domestic animals. It continues to be a major problem in human beings in underdeveloped countries, and it is on the rise in some industrialized nations, largely because of the immunosuppressive effects of AIDS,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

immigration, and movement of infected animals across borders. The World Health Organization (WHO) estimated that 30 million people, mostly in developing countries, died of tuberculosis between 1990 and 1999. *Mycobacterium tuberculosis* is transmitted between human beings, but where unpasteurized cow's milk is consumed, *Mycobacterium bovis* from the milk of cattle with mammary tuberculosis is also important.

Cattle can be infected with *Mycobacterium bovis*, *Mycobacterium tuberculosis*, and *Mycobacterium avium-intracellulare* complex (*Mycobacterium avium* ssp. *avium*, *Mycobacterium avium* ssp. *silvaticum*, *Mycobacterium avium* ssp. *paratuberculosis*, and *Mycobacterium avium* ssp. *intracellulare*) by several routes, but infection of the lungs by inhalation of *Mycobacterium bovis* is the most common in adult animals, whereas ingestion of infected milk is more predominant in young animals.

Respiratory infection usually starts when inhaled bacilli reach the alveoli and are phagocytosed by pulmonary alveolar macrophages. If these cells are successful in destroying the bacteria, infection is averted. However, *Mycobacterium bovis*, being a facultative pathogen of the monocytic-macrophagic system, may multiply intracellularly, kill the macrophage, and initiate infection. From this first nidus of infection, bacilli spread aerogenously via airways within the lungs and eventually via the lymph vessels to tracheobronchial and mediastinal lymph nodes.

The initial focus of infection at the portal of entry (lungs) plus the involvement of regional lymph nodes is termed the primary (Ghon) complex of tuberculosis. If the infection is not contained within this primary complex, bacilli disseminate via the lymph vessels to distant organs and other lymph nodes by the migration of infected macrophages. Hematogenous dissemination occurs sporadically when the inflammatory process containing the mycobacteria erodes the walls of blood vessels and causes vasculitis. If bacterial dissemination is sudden and massive, numerous small foci of infection develop in many tissues and organs and is referred to as miliary tuberculosis (like millet seeds). The host becomes hypersensitive to the mycobacterium, which enhances the cell-mediated immune defenses in early or mild infections but can result in host-tissue destruction in the form of caseous necrosis. The evolution and dissemination of the pulmonary infection are closely regulated by cytokines and TNF- $\alpha$  production by alveolar macrophages.

526

527

Unlike abscesses that tend to grow rather fast, granulomas evolve slowly at the site of infection. The lesion starts with few macrophages and neutrophils ingesting the offending organism, but because mycobacterium organisms are resistant to phagocytosis, infected macrophages eventually die, releasing viable bacteria, lipids, and cell debris. Cell debris accumulates in the center of the lesion, whereas viable bacteria and bacterial lipids attract additional macrophages and a few lymphocytes at the periphery of the lesion. Some of these newly recruited macrophages are activated by local lymphocytes and become large phagocytic cells with abundant cytoplasm resembling epithelial cells, thus the term *epithelioid cells*. Multinucleated macrophages also appear at the edges of the lesion, and finally the entire focal inflammatory process becomes surrounded by fibroblasts and connective tissue. It may take weeks or months for a granuloma to be grossly visible.

Bovine tuberculosis, the prototype for granulomatous pneumonia, is characterized by the presence of a few or many caseated granulomas (Fig. 9-57). The early gross changes are small foci (tubercles) most frequently seen in the dorsocaudal, subpleural areas. With progression, the lesions enlarge and become confluent with the formation of large areas of caseous necrosis. Calcification of the granulomas is a typical finding in bovine tuberculosis. Single nodules or clusters occur on the pleura and peritoneum, and this presentation has been termed pearl disease. Microscopically the tubercle is composed of mononuclear cells of various types. In young tubercles, which are noncaseous, epithelioid and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Langhans' giant cells are at the center, surrounded by lymphocytes, plasma cells, and macrophages. Later, caseous necrosis is at the center, secondary to the effects of cell-mediated hypersensitivity, enclosed by other cell types and fibrosis at the periphery. Acid-fast organisms may be numerous but, more often are difficult to find in histologic section or smears.

Clinically the signs relate to the dysfunction of a particular organ system or to general debilitation, reduced milk production, and emaciation. In the pulmonary form, which is more than 90% of bovine cases, a chronic, moist cough can progress to dyspnea. Enlarged tracheobronchial lymph nodes can contribute to the dyspnea by impinging on airways, and the enlargement of caudal mediastinal nodes can compress the caudal thoracic esophagus and cause bloating.

9.2.3.9.2.8

### *Mycoplasma bovis* pneumonia

*Mycoplasma bovis* is the most common *Mycoplasma* sp. isolated from pneumonic lungs of cattle in Europe and North America. Pulmonary infection is exacerbated by stress or any other adverse factor (e.g., viral infection) that depresses the pulmonary defense mechanisms. Lung lesions are those of a chronic necrotizing bronchopneumonia. The microscopic lesions consist of distinct areas of pulmonary necrosis surrounded by a rim of neutrophils, macrophages, and fibroblasts. The diagnosis is confirmed by isolation or immunohistochemical labeling of tissue sections for *Mycoplasma* antigens. *Mycoplasma bovis* has also been incriminated in arthritis, otitis, mastitis, abortion, and keratoconjunctivitis.

9.2.3.9.2.9

### Interstitial pneumonias of cattle

Atypical interstitial pneumonia (AIP) is a vague clinical term well entrenched in veterinary literature, but one that has led to enormous confusion among veterinarians. It was first used to describe acute or chronic forms of bovine pneumonia that did not fit in any of the “classical” forms because of the lack of exudate and lack of productive cough. Microscopically the criteria for diagnosis of AIP in cattle were based on the absence of obvious exudate and the presence of edema, interstitial emphysema (see Pulmonary Emphysema), hyaline membranes, hyperplasia of type II pneumonocytes, and interstitial fibrosis with cellular infiltrates. At that time, any pulmonary disease or pulmonary syndrome that had a few of the above lesions was traditionally diagnosed as AIP, and grouping all these different syndromes together was inconsequential because their etiopathogenesis were then unknown.

Field and laboratory investigations have demonstrated that most of the bovine syndromes previously grouped under AIP have rather different causes and pathogeneses (Fig. 9-65). Further, what was “atypical” in the past has become so routine that it is fairly common nowadays to find “typical cases” of AIP. For all these reasons, investigators, largely from Britain, proposed that all these syndromes previously clustered into AIP should be named according to their specific cause or pathogenesis. The most common bovine syndromes characterized by edema, emphysema, hyaline membranes, and hyperplasia of type II pneumonocytes include bovine pulmonary edema and emphysema (fog fever), “extrinsic allergic alveolitis” (hypersensitivity pneumonitis), “reinfection syndrome” (hypersensitivity to *Dictyocaulus* sp. or BRSV), milk allergy, ingestion of moldy potatoes, and others.

9.2.3.9.2.9.1

### Acute bovine pulmonary edema and emphysema (fog fever).

Acute bovine pulmonary edema and emphysema (ABPE), known in Britain as fog fever (no association with atmospheric conditions), occurs in cattle usually grazing “fog” pastures (that is, aftermath or foggage, regrowth after a hay or silage has been cut). Epidemiologically, ABPE usually

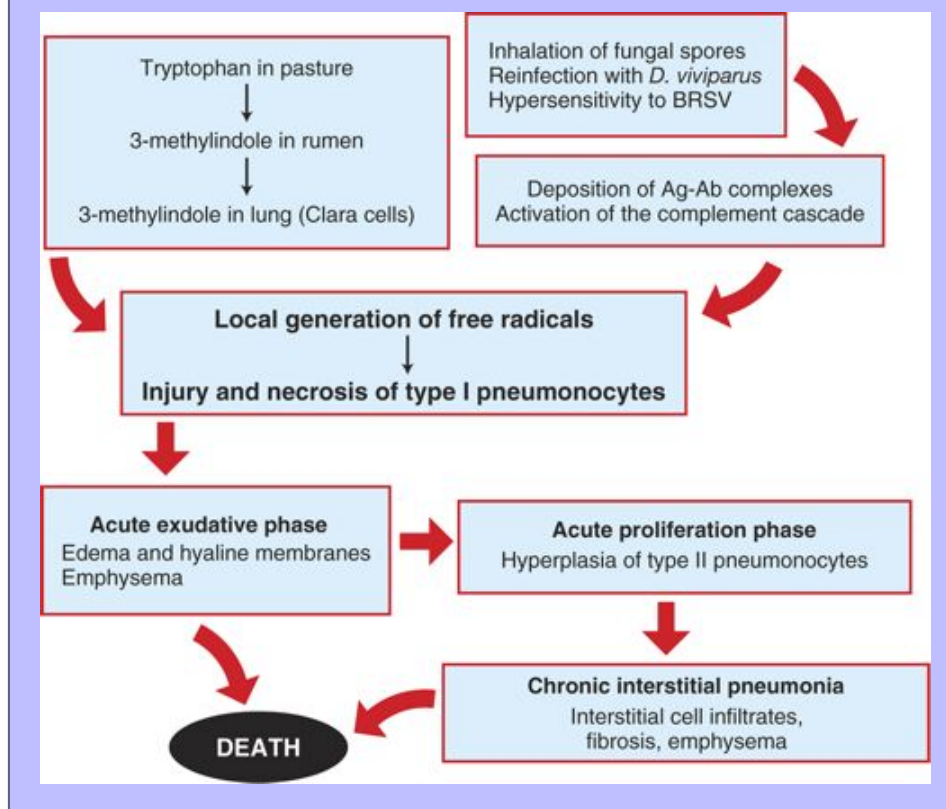

## Pathologic Basis of Veterinary Disease, 4th Edition

occurs in adult beef cattle in the fall when there is a change in pasture, from a short, dry grass to a lush, green grass. It is generally accepted that L-tryptophan present in the pasture is metabolized in the rumen to 3-methylindole, which in turn is absorbed into the blood stream and carried to the lungs. Mixed function oxidases present in the nonciliated bronchiolar epithelial (Clara) cells metabolize 3-methylindole into a highly pneumotoxic compound that causes extensive necrosis of bronchiolar cells and type I pneumocytes (Fig. 9-65), and increases alveolar permeability leading to edema, interstitial pneumonia, and alveolar and interstitial emphysema.

527

528

**Fig. 9-65 Schematic diagram of the pathogenesis of toxic and allergic pneumonias (“atypical interstitial pneumonia”) in cattle.** BRSV, Bovine respiratory syncytial virus. (Redrawn with permission from Dr. A. López, Atlantic Veterinary College.)

The gross lesions are those of a diffuse interstitial pneumonia with severe alveolar and interstitial edema and interlobular emphysema (Fig. 9-35). The lungs are enlarged, pale, and rubbery in texture, and the lesions are most notable in the caudal lobes. Microscopically the lesions are alveolar and interstitial edema and emphysema, formation of hyaline membranes within alveoli, and in those animals that survive for several days, hyperplasia of type II alveolar epithelial cells.

Clinically, severe respiratory distress develops within 2 weeks of the pasture change, and cattle develop expiratory dyspnea, oral breathing, and evidence of emphysema within the lungs and even

## Pathologic Basis of Veterinary Disease, 4th Edition

subcutaneously along the back. Experimentally, reducing ruminal conversion of L-tryptophan to 3-methylindole prevents the development of ABPE.

A number of other agents cause virtually the same clinical and pathologic syndrome as is seen in ABPE. The pathogenesis is assumed to be similar, although presumably other toxic factors will be specific for each syndrome. One of these pneumotoxic factors is 4-ipomeanol, which is found in moldy sweet potatoes contaminated with the fungus *Fusarium solani*. Mixed-function oxidases in the lungs activate 4-ipomeanol into a potent pneumotoxicant capable of producing irreversible injury to type I pneumonocytes and bronchiolar epithelial cells. Similarly, purple mint (*Perilla frutescens*), stinkwood (*Zieria arborescens*), and rapeseed and kale (*Brassica* species) also cause pulmonary edema, emphysema, and interstitial pneumonia.

9.2.3.9.2.9.2

### Extrinsic allergic alveolitis.

Extrinsic allergic alveolitis (hypersensitivity pneumonitis), one of the most common allergic diseases in cattle, is seen mainly in housed, adult dairy cows in the winter. This disease shares many similarities with its human counterpart known as farmer's lung, which results from a type III hypersensitivity reaction to inhaled organic antigens most commonly fungal spores, mainly of the thermophilic actinomycete, *Saccharopolyspora rectivirgula* (*Micropolyspora faeni*), commonly found in moldy hay. This is followed by an antibody response to inhaled fungal spores and local deposition of antigen-antibody complexes (Arthus reaction) in the lungs (Fig. 9-65). Because it occurs only in a few animals of the herd or a sporadic farmer, it is presumed that intrinsic host factors such as dysregulation of IgG, interleukins, IFN- $\gamma$  and T lymphocytes are involved in the pathogenesis of the disease. Clinically, it can be acute or chronic; the latter has a cyclical pattern of exacerbation during winter months. Weight loss, coughing, and poor exercise tolerance are clinical features.

528

529

Grossly the postmortem lesions vary from subtle, gray, subpleural foci (granulomatous inflammation) to severe, in which the lungs are firm and heavy and have a "meaty appearance" because of alveolar epithelial hyperplasia, lymphocytic infiltration, and interstitial fibrosis. Characteristically, discrete noncaseous granulomas formed in response to the deposition of antigen-antibody complexes are scattered throughout the lungs. Chronic cases of extrinsic allergic alveolitis can eventually progress to diffuse fibrosing alveolitis. Full recovery can occur if it is recognized and treated at the early stages of the disease.

Hypersensitivity to reinfection with larvae of *Dictyocaulus viviparus* is another allergic syndrome manifested in the lungs that cause signs and lesions indistinguishable from ABPE, with the exception of a component of eosinophils and possibly larvae seen microscopically in the alveolar exudate. It has been suggested that emphysema with diffuse proliferative alveolitis and formation of hyaline membranes can also occur in the late stages of BRSV infection in cattle. Presumably, this disease shares many similarities with "atypical" infections occasionally seen in children with respiratory syncytial virus (RSV human strain), in which a hypersensitivity to the virus or virus-induced augmentation of the immune response results in allergic interstitial pneumonia (Fig. 9-65).

## Pathologic Basis of Veterinary Disease, 4th Edition

9.2.3.9.2.9.3

### Other forms of bovine interstitial pneumonia.

Milk allergy, a type of systemic anaphylaxis (type I hypersensitivity) in cows sensitized to their own milk casein and lactalbumin, can cause acute pulmonary congestion, edema, and even hemorrhage and emphysema. Occasionally, adverse drug reactions can induce a similar allergic response in the lung.

Inhalation of manure (“pit”) gases, such as hydrogen sulfide (H<sub>2</sub>S), ammonia (NH<sub>3</sub>), and nitrogen dioxide (NO<sub>2</sub>) from silos, can be a serious hazard to animals and human beings. At toxic concentrations, these gases cause necrosis of bronchiolar cells and type I pneumonocytes, a fulminating pulmonary edema that causes asphyxiation, and rapid death (Fig. 9-39). Like other oxidant gases, inhalation of NO<sub>2</sub> also causes bronchiolitis, edema, and interstitial pneumonia and in survivors, bronchiolitis obliterans (“silo filler’s disease”).

Smoke inhalation resulting from barn or house fires is sporadically seen by veterinarians and pathologists. In addition to skin burns and asphyxiation, animals involved in fire accidents suffer extensive thermal injury produced by the heat on the nasal and laryngeal mucosa, and severe chemical irritation caused by inhalation of combustion gases and particles in the lung. Animals that survive or are rescued from fires frequently develop nasal, laryngeal, and tracheal edema, and pulmonary hemorrhage and alveolar edema, which are caused by chemical injury to the blood-air barrier. Microscopic examination of the lungs often reveals carbon particles (soot) on mucosal surfaces of the conducting system.

9.2.3.9.2.10

### Parasitic pneumonias of cattle

9.2.3.9.2.10.1

#### Verminous pneumonia (*Dictyocaulus viviparus*).

Pulmonary lesions in parasitic pneumonias (the word is used here in its restricted sense to mean helminth infestations of the lungs) vary from interstitial in larval migration to chronic bronchitis, which is caused by some intrabronchial adult parasites, to granulomatous pneumonia, which is caused by dead larvae, aberrant parasites, or eggs of parasites. In many cases, an “eosinophilic syndrome” in the lungs is characterized by infiltrates of eosinophils in the pulmonary interstitium and bronchoalveolar spaces and by blood eosinophilia. Atelectasis and emphysema secondary to the obstruction of airways are also common findings in parasitic pneumonias. The severity of these lesions relates to the numbers and size of the parasites and the nature of the host reaction, which sometimes includes hypersensitivity reactions. A common general term for all of these diseases is verminous pneumonia, and the adult nematodes are often visible grossly in the airways (Fig. 9-66).

*Dictyocaulus viviparus* is an important pulmonary nematode (lungworm) responsible for a disease in cattle referred to as verminous pneumonia or verminous bronchitis. Adult parasites live in the bronchi of cattle, mainly in those of the caudal lobes of the lungs. Adult parasites cause severe bronchial irritation, bronchitis, and pulmonary edema, which in turn is responsible for lobular atelectasis and interstitial emphysema. Atelectasis is clearly confined to the lobules of the lungs ventilated by the obstructed bronchi (dorsocaudal). Interstitial emphysema (interlobular) is caused by forced expiratory movements against a partially obstructed single bronchus. In addition to the inflammation of bronchial mucosa, bronchoaspiration of larvae and eggs also causes an influx of

529  
530

## Pathologic Basis of Veterinary Disease, 4th Edition

---

leukocytes into the bronchoalveolar space (alveolitis). Verminous pneumonia is most commonly seen in calves during their first summer grazing pastures that are used repeatedly from year to year, particularly in regions of Europe that have a moist, cool climate. The parasite can overwinter in pastures, even in climates as cold as Canada's, and older animals may be carriers for a considerable length of time.

**Fig. 9-66 Verminous pneumonia (*Dictyocaulus viviparus*), bronchus, calf.** The bronchus contains numerous slender lungworms and large amounts of clear foamy fluid, indicative of pulmonary edema. (Courtesy Ontario Veterinary College.)

At necropsy, lesions appear as large, dark or gray, depressed, wedge-shaped areas of atelectasis present usually along the dorsocaudal aspect of the lungs. On a cut surface, edematous foam and mucus mixed with white, slender (up to 80-mm long) nematodes are visible in the bronchi (Fig. 9-66). In most severe cases, massive numbers of nematodes fill the bronchial tree. Microscopically the bronchial lumens are filled with parasites admixed with mucus because of goblet cell hyperplasia, and there is also squamous metaplasia of the bronchial and bronchiolar epithelium because of chronic irritation. There is also alveolar edema; hyperplasia of BALT caused by a persistent immunologic stimulus; hypertrophy and hyperplasia of bronchiolar smooth muscle because of increased contraction and decreased muscle relaxation; and a few eosinophilic granulomas around the eggs and dead larvae. These granulomas, grossly, are gray, noncaseated nodules (2 to 4 mm in diameter) and may be confused with those caused by tuberculosis.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The clinical signs (coughing) vary with the severity of infection, and severe cases can be confused clinically with interstitial pneumonias. Expiratory dyspnea and death can occur with heavy parasitic infestations when there is massive obstruction of airways.

A different form of bovine pneumonia, an acute allergic reaction known as reinfection syndrome, occurs when previously sensitized adult cattle are exposed to large numbers of larvae (*Dictyocaulus viviparus*). Lesions in this syndrome are those of a hypersensitivity pneumonia as previously described.

9.2.3.9.2.10.2

### Other lung parasites.

*Ascaris suum* is the common intestinal roundworm of pigs; larvae cannot complete their life cycle in calves, but the larvae can cause severe pneumonia and death within 2 weeks if calves are housed in places where infested pigs were previously kept. Pigs, the natural host, also can be killed if exposed to an overwhelming larval migration. Clinical signs because of migration of larvae through the lungs include cough and expiratory dyspnea to the point of oral breathing. The gross lesions are of a diffuse interstitial pneumonia with hemorrhagic foci, atelectasis, and interlobular edema and emphysema (Fig. 9-54). Microscopically, there are focal intraalveolar hemorrhages caused by migratory larvae, which in some cases can be seen in bronchioles and alveoli admixed with edematous fluid and cellular exudate (including eosinophils). The alveolar walls are thickened because of edema and few inflammatory cells.

Hydatid cysts, the intermediate stage of *Echinococcus granulosus*, can be found in the lungs and liver and other viscera of sheep and to a lesser extent in cattle, pigs, goats, horses, and human beings. The adult stage is a tapeworm that parasitizes the intestine of Canidae. Hydatidosis is still an important zoonosis in some countries, and perpetuation of the parasite life cycle results from animals being fed uncooked offal from infected sheep and consumption of uninspected meat. Hydatid cysts are generally 5 to 15 cm in diameter and numerous cysts can be found in the viscera of affected animals (Fig. 9-67); they have little clinical significance in animals but are of economic importance because of carcass condemnation.

9.2.3.9.2.11

### Aspiration pneumonias of cattle

The inhalation of regurgitated ruminal contents or iatrogenic deposition of medicines or milk into the trachea can cause severe and often fatal aspiration pneumonia. Bland substances such as mineral oil may incite only a mild suppurative or histiocytic bronchopneumonia, whereas some “home remedies” or ruminal contents are highly irritating and cause a fibrinous, necrotizing bronchopneumonia. The right lung tends to be more severely affected because the right cranial bronchus is closest to the trachea. However, the distribution may vary when animals aspirate while in lateral recumbency. In some severe cases, pulmonary necrosis can be complicated by infection with saprophytic organisms present in ruminal contents, causing fatal gangrenous pneumonia. Aspiration pneumonia should always be considered in animals with cleft palate or in those whose swallowing has been compromised because of disorders such as hypocalcemia (milk fever). On the other hand, neurological diseases such as encephalitis (e.g., rabies) or encephalopathy (e.g., lead poisoning) should be investigated in animals in which the cause of aspiration pneumonia could not be explained otherwise. Depending on the nature of the aspirated material, histopathologic evaluation generally reveals foreign particles such as vegetable cells, milk droplets, and large numbers of bacteria in bronchi, bronchioles and alveoli. Vegetable cells

530

531

## Pathologic Basis of Veterinary Disease, 4th Edition

and milk typically induce an early neutrophilic response followed by a histocytic reaction with “foreign body” multinucleated giant cells. Special stains are used for the microscopic confirmation of aspirated particles in the lung (e.g., PAS for vegetable cells and O-red oil for oil or milk droplets).

**Fig. 9-67 Hydatidosis (echinococcosis), lung, sheep.** A large hydatid cyst is present in the pulmonary parenchyma. *Inset:* Hydatid cyst, cut-open section. The cyst contains fluid and larvae and is often enclosed by a fibrous capsule. (**Figure and Inset**, Courtesy Dr. Manuel Quezada, Universidad de Concepci-n, Chile.)

9.2.3.9.3

### Pneumonias of Sheep and Goats

In the past, *Pasteurella haemolytica* was incriminated in four major ovine diseases known as acute ovine pneumonic pasteurellosis (shipping fever), enzootic pneumonia (nonprogressive chronic pneumonia), fulminating septicemia, and mastitis. Under the new nomenclature, *Mannheimia haemolytica* (biotype A) is now responsible for ovine pneumonia resembling shipping fever in cattle (ovine pneumonic mannheimiosis), septicemia in young lambs (under 3 months of age), and ovine enzootic pneumonia and sporadic severe gangrenous mastitis in ewes. *Pasteurella trehalosi* (formerly *Pasteurella haemolytica* biotype T) is the agent incriminated with septicemia in lambs 5 to 12 months old.

9.2.3.9.3.1

#### Ovine pneumonic mannheimiosis

Ovine pneumonic mannheimiosis is one of the most common and economically significant diseases in most areas where sheep are raised. It is caused by *Mannheimia haemolytica* (biotype A) and has pathogenesis and lesions similar to those of pneumonic mannheimiosis of cattle. Colonization and infection of lungs are facilitated by stressors such as changes in weather, handling, deworming, dipping, and by viral infections such as PI-3 virus, RSV, adenovirus, and probably chlamydia and *Bordetella parapertussis*. Lesions are characterized by a severe fibrinous bronchopneumonia (lobar,

## Pathologic Basis of Veterinary Disease, 4th Edition

cranioventral) with pleuritis (Fig. 9-68). Subacute to chronic cases appear as a fibrinopurulent bronchopneumonia, and sequelae include abscesses and fibrous pleural adhesions.

**Fig. 9-68 Acute fibrinous bronchopneumonia (pleuropneumonia), pneumonic mannheimiosis (*Mannheimia haemolytica*), lungs, lamb.** The cranioventral aspects of the lung are red, swollen, and very firm (consolidated) with some fibrin on the pleural surface. Note that the consolidated lung resembles liver, hence the previous name of “lung hepatization.” (Courtesy Ontario Veterinary College.)

### 9.2.3.9.3.2

#### Chronic enzootic pneumonia

In sheep, this entity is a multifactorial disease complex that, in contrast to ovine pneumonic mannheimiosis, causes only a mild to moderate pneumonia, and it is rarely fatal. It generally affects animals younger than 1 year of age. Significant costs associated with chronic enzootic pneumonia include reduction of weight gain, labor costs, veterinary fees, and slaughterhouse waste. The modifier “chronic” is used here to avoid any confusion with pneumonic mannheimiosis (“acute enzootic pneumonia”). It is also sometimes called atypical pneumonia, chronic nonprogressive pneumonia, proliferative pneumonia, or other names.

Chronic enzootic pneumonia is a clinicoepidemiologic term and does not imply a single causal agent, but a combination of infectious, environmental, and managerial factors. The list of infectious agents involved in ovine enzootic pneumonia includes *Mannheimia haemolytica*, *Pasteurella multocida*, PI-3, adenovirus, reovirus, RSV, chlamydia, and mycoplasmas (*Mycoplasma ovipneumoniae*).

In the early stages of the disease, a cranioventral bronchointerstitial pneumonia is characterized by moderate thickening of alveolar walls because of hyperplasia of type II pneumonocytes. In some cases, when further colonization of the lungs with secondary pathogens such as *Pasteurella multocida* takes place it may progress to fibrinous or suppurative bronchopneumonia (Fig. 9-69). One might expect some specific evidence pointing to the infectious agents (for example, large intranuclear inclusion bodies in epithelial cells with adenoviral infection), but such is often not the case, either because examination is seldom done at the acute stage when the lesions are still present or because secondary bacterial infections mask the primary lesions. In the late stages, chronic enzootic pneumonia is characterized by hyperplastic bronchitis, atelectasis, alveolar and bronchiolar fibrosis, and severe peribronchial lymphoid hyperplasia (cuffing pneumonia).

531

532

**Fig. 9-69 Acute fibrinosuppurative bronchopneumonia (*Pasteurella multocida*), lung, sheep.** The ventral portions of the cranial, middle, and caudal lobes are consolidated (C), involving approximately 50% of the lung. The dorsal portion of the caudal lung is relatively normal (N) but is multifocally congested and edematous. (Courtesy Dr. J. Andrews, College of Veterinary Medicine, University of Illinois.)

### 9.2.3.9.3.3

#### Septicemic pasteurellosis

This condition is a common ovine disease caused by *Pasteurella trehalosi* (biotype T) in animals 5 months or older, or by *Mannheimia haemolytica* (biotype A) in lambs younger than 2 months of age. Both organisms are carried in the tonsils and oropharynx of normal sheep; but, under abnormal circumstances, bacteria can invade adjacent tissues, enter the blood stream, and cause septicemia, particularly in association with stresses such as dietary or environmental changes. Affected animals die after a short illness and only rarely have clinical signs such as dullness, recumbency, and dyspnea.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Gross lesions include a distinctive necrotizing pharyngitis and tonsillitis, severe congestion and edema of the lungs, focal hepatic necrosis, infarcts and petechiae in the tongue, esophagus, and intestine, but particularly in the lungs and pleura. Microscopically, the hallmark lesion is a disseminated intravascular thrombosis often associated with the presence of bacterial colonies in the capillaries of affected tissues. *Mannheimia haemolytica* and *Pasteurella trehalosi* are readily isolated from many organs.

### 9.2.3.9.3.4

#### Contagious caprine pleuropneumonia

This disease in goats is the counterpart of contagious bovine pleuropneumonia in cattle; sheep do not have a corresponding disease. The etiopathogenesis and geographic distribution of contagious caprine pleuropneumonia are yet to be determined. Three mycoplasmas, namely *Mycoplasma mycoides* ssp. *mycoides* large colony type, *Mycoplasma mycoides* ssp. *capri*, and *Mycoplasma capricolum* ssp. *capripneumoniae*, have been associated with respiratory infections in goats; however, only the last is considered as the etiologic agent of typical contagious caprine pleuropneumonia.

Caprine pleuropneumonia is important in Africa, the Middle East, and parts of Asia but is also seen elsewhere. *Mycoplasma mycoides* ssp. *mycoides* large colony type and *Mycoplasma mycoides* ssp. *capri* are present in North America and have been isolated from respiratory diseases of goats. Although it is unwise to speak in absolute terms when dealing with many aspects of biology, transmission from goats to sheep or cattle does not occur to any significant degree.

Clinically the disease is similar to contagious bovine pleuropneumonia, with high morbidity and mortality, fever, cough, dyspnea, and increasing distress and debility. The gross lesions caused by *Mycoplasma capricolum* ssp. *capripneumoniae* are similar to those in the bovine disease and consist of a severe fibrinous bronchopneumonia and pleuritis; however, distention of the interlobular septa and formation of pulmonary sequestra are less obvious than in the bovine disease. Fibrinous polyarthritis, septicemia, meningitis, mastitis, peritonitis, and abortion are other possible manifestations of disease caused by *Mycoplasma mycoides* ssp. *mycoides* large colony type and *Mycoplasma mycoides* ssp. *capri*. The pathogenicity of other mycoplasmas such as *Mycoplasma ovipneumoniae*, *Mycoplasma arginini*, and *Mycoplasma capricolum* ssp. *capricolum* in sheep and goats is still being defined, and specific description of the lesions would be premature. These organisms probably cause disease only in circumstances similar to those for enzootic pneumonia, where host, infectious, and environmental factors play a complex interaction in the pathogenesis of the disease. Most recently, it has been suggested that IgG antibodies directed against ovine mycoplasmal antigens cross-react with ciliary proteins causing inflammation and ciliary dysfunction, a condition in lambs referred to as “coughing syndrome.”

532

533

### 9.2.3.9.3.5

#### Maedi (maedi-visna)

This entity is an important, lifelong, persistent viral disease of sheep and occurs in most countries, except Australia and New Zealand. Maedi means “shortness of breath” in the Icelandic language, and it is known as Graaff-Reinet disease in South Africa, Zwoegerziekte in The Netherlands, la bouhite in France, and ovine (Montana or Marsh's) progressive pneumonia (OPP) in the United States. More recently, the disease has also been referred to as ovine lentivirus-induced lymphoid interstitial pneumonia or simply, lymphoid interstitial pneumonia (LIP).

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Maedi is caused by a nononcogenic retrovirus of the lentivirus subfamily (ovine lentivirus) antigenically related to the retrovirus causing caprine arthritis-encephalitis. Seroepidemiologic studies indicate that infection is widespread in the sheep population, yet the clinical disease seems to be rare. The pathogenesis is incompletely understood, but it is known that transmission occurs largely through ingestion of infected colostrum and to a lesser extent by close contact between infected and susceptible sheep. Once in the body, the ovine lentivirus remains for long periods of time within monocytes and macrophages, including alveolar and pulmonary intravascular macrophages; clinical signs do not develop until after a long incubation period of 2 years or more.

Pulmonary lesions at the time of death are a severe interstitial pneumonia, and the lungs fail to collapse when the thorax is opened. Notable rib imprints, indicators of expanded lungs, are often present on the pleural surface. The lungs are pale and mottled (Fig. 9-70) and typically heavy (2 to 3 times normal weight), and the tracheobronchial lymph nodes are enlarged. Microscopically, the interstitial pneumonia is characterized by BALT hyperplasia and thickening of alveolar walls and peribronchial interstitial tissue by heavy infiltration of lymphocytes, largely T lymphocytes (Fig. 9-53). Recruitment of mononuclear cells into the pulmonary interstitium is presumably the result of sustainable production of cytokines by retrovirus-infected pulmonary macrophages and lymphocytes. Hyperplasia of type II pneumocytes is not a prominent feature of maedi, but there is some fibrosis and smooth muscle hypertrophy in bronchioles. Secondary bacterial infections often confound the microscopic lesions of the disease. Enlargement of regional lymph nodes (tracheobronchial) is because of severe lymphoid hyperplasia, primarily of B lymphocytes. The virus also can infect many other tissues, causing nonsuppurative encephalitis (visna), lymphocytic arthritis, lymphofollicular mastitis, and vasculitis.

**Fig. 9-70 Interstitial pneumonia (unknown etiology), lung, sheep.** The lung is heavy, rubbery, and shows costal (rib) imprints on the pleural surface. The diffuse distribution is typical of interstitial pneumonia. The trachea contains some edema fluid. (Courtesy Western College of Veterinary Medicine.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Maedi is clinically characterized by dyspnea and an insidious, slowly progressive emaciation despite good appetite. Death is inevitable once clinical signs are present, but may take many months.

9.2.3.9.3.6

### Caprine arthritis-encephalitis (CAE)

This retroviral disease of goats (lentivirus) has a pathogenesis remarkably similar to that of maedi-visna in sheep. It was first described in the United States in the 1970s, but also occurs in Canada, Europe, Australia, and probably elsewhere. This disease has two major clinicopathologic forms: One involves the central nervous system of goat kids and young goats and is characterized by a nonsuppurative leukoencephalomyelitis; the other form involves the joints of adult goats and is characterized by a chronic, nonsuppurative arthritis-synovitis. In addition, infection with CAE virus can cause chronic lymphocytic interstitial pneumonia.

The lentivirus of CAE is closely related to the maedi-visna virus, and, in fact, cross infection with CAE virus in sheep has been achieved experimentally. Similar to maedi, CAE infection presumably occurs during the first weeks of life when the doe transmits the virus to her offspring through infected colostrum or milk. Horizontal transmission between infected and susceptible goats has also been described. After coming into contact with mucosal cells at the portal of entry, the virus initially replicates in monocytes-macrophages. Infected macrophages are disseminated hematogenously to the central nervous system, joints, lungs, and mammary glands. Like maedi, there is some evidence that the recruitment of lymphocytic cells results from dysregulation of cytokine production by infected macrophages and lymphocytes in affected tissues. It can take several months before serum antibodies can be detected in infected goats. Recent reports indicate that CAE antibodies cross-react with CAE and HIV retroviruses.

533

534

Grossly a diffuse interstitial pneumonia tends to be most severe in the caudal lobes. The lungs are gray-pink and firm in texture with numerous, 1- to 2-mm, gray-white foci on the cut surface (Fig. 9-71). The tracheobronchial lymph nodes are consistently enlarged. Microscopically, thickening of the alveolar wall is present because of infiltration of lymphocytes and conspicuous hyperplasia of type II pneumonocytes. One important difference between CAE pneumonia and maedi is that pulmonary lesions in goats may be accompanied by accumulation of proteinaceous eosinophilic material in the alveoli, which in electron micrographs has structural features of pulmonary surfactant. The pulmonary form of CAE can be mistaken for parasitic pneumonia (*Muellerius capillaris*), as these two diseases share some macroscopic similarities and the two diseases can coexist in the same goat.

Clinically, goats are active and afebrile but progressively lose weight in spite of normal appetite. The encephalitic or arthritic signs tend to obscure the respiratory signs, which are only evident on exertion. Secondary bacterial infections are common in affected animals.

**Fig. 9-71 Interstitial pneumonia with alveolar proteinosis, lung, cut surface sheep.** Note the gray nodules (arrows) and meaty appearance of the lung. These lesions are seen in sheep with the caprine arthritis-encephalitis-pneumonia disease complex. (Courtesy Dr. J.M. King College of Veterinary Medicine, Cornell University.)

9.2.3.9.3.7

### Tuberculosis

This disease is uncommon in sheep and goats, but infection with *Mycobacterium bovis* or with the *Mycobacterium avium* complex does occur when the disease is prevalent in other species in the locality. The pulmonary form, similar to that seen in cattle, is characterized by a granulomatous pneumonia with multiple, large, caseous, calcified, and well-encapsulated granulomas scattered throughout the lungs. Intralesional acid-fast organisms within macrophages are not as abundant as in bovine tuberculosis.

9.2.3.9.3.8

### Parasitic pneumonias of sheep and goats

*Dictyocaulus filaria* is a serious, worldwide, parasitic disease of the lungs, most commonly of lambs and goat kids, but occurring in adults as well. The life cycle and lesions are similar to those of *Dictyocaulus viviparus* of cattle. The clinical signs (cough, moderate dyspnea, and loss of condition) and lesions relate mainly to obstruction of the small bronchi by adult worms and filaria. As seen in cattle with *Dictyocaulus viviparus*, areas of atelectasis secondary to bronchiolar obstruction are present

## Pathologic Basis of Veterinary Disease, 4th Edition

particularly along the dorsal caudal lungs. Microscopically, affected lungs are characterized by a catarrhal, eosinophilic bronchitis, with peribronchial lymphoid hyperplasia, thickening of alveolar interstitium as a result of hyperplasia of type II pneumocytes, and focal infiltration of lymphocytes. Bronchioles and alveoli contain edematous fluid, eosinophils, and parasitic larvae and eggs. Anemia of undetermined pathogenesis and secondary bacterial pneumonia are common in small ruminants with this parasitic disease.

*Muellerius capillaris*, also called the nodular lungworm, occurs in sheep and goats in most areas of the world and is the most common lung parasite of sheep in Europe and Northern Africa. It requires slugs or snails as intermediate hosts. Clinical signs are usually not apparent. The lesions in sheep are typically multifocal, subpleural nodules that tend to be most numerous in the dorsal areas of the caudal lung lobes (Fig. 9-72). These nodules are soft and hemorrhagic in the early stages, but later become gray-green and hard or even calcified. Microscopically, a focal, eosinophilic, and granulomatous reaction occurs in the subpleural alveoli where the adults, eggs, and larvae reside.

Goats differ from sheep by having diffuse interstitial rather than focal lesions, and the reaction to the parasites seen microscopically varies from almost no lesions to a severe interstitial pneumonia with heavy infiltrates of mononuclear cells in alveolar walls resembling CAE or mycoplasmal infections. Secondary effects of *Muellerius capillaris* infection in sheep and goats include decreased weight gain and, possibly, secondary bacterial infections.

*Protostrongylus rufescens* is a worldwide parasite of sheep and goats. It requires an intermediate snail as a host. Infection is usually subclinical, but *Protostrongylus rufescens* can be pathogenic for lambs and goat kids, and can cause anorexia, diarrhea, weight loss, and mucopurulent nasal discharge. The adult parasite lives in bronchioles as *Dictyocaulus* spp., but it causes pulmonary nodules similar to those of *Muellerius capillaris*.

534

535

9.2.3.9.4

### Pneumonias of Pigs

Porcine pneumonias are unequivocally a major component of the problems facing the contemporary swine industry. The incidence, prevalence, and mortality rates of pneumonias in pigs are dependent on a series of complex, multifactorial interactions. Among the most commonly recognized elements linked to porcine pneumonias are the following:

- Host (age, genetic makeup, immune status)
- Infectious agents (viruses, bacteria, mycoplasmas)
- Environmental determinants (humidity, temperature, ammonia concentrations)
- Management practices (crowding, mixing of animals, air quality, nutrition, stress)

Because of the nature of these multifactorial interactions, it will become obvious in the following paragraphs that more often than not a specific type of pneumonia frequently progresses to, or coexists with, another one.

9.2.3.9.4.1

### Swine influenza

It is generally accepted that this pig disease resulted from adaptation of the type A influenza virus, the cause of the human influenza pandemic during World War I. Swine influenza is enzootic worldwide and is known to infect human beings who are in close contact with sick pigs. Infection between pigs occurs mainly by aerosols or oral route; however, the virus can also be transmitted by lungworms and the common earthworm (when ingested). The infection of epithelial cells spreads rapidly throughout the nasal, tracheal, and bronchial mucosa, with the more severe outbreaks reflecting more involvement of intrapulmonary airways and secondary infection with *Pasteurella multocida*, *Arcanobacterium pyogenes*, or *Haemophilus* spp.

Pulmonary lesions caused by influenza virus alone are rarely seen in the postmortem room because this disease has very low mortality unless complicated with secondary bacterial infections. Grossly a copious catarrhal to mucopurulent inflammation extends from the nasal passages to the bronchioles, the volume of mucus being sufficient to plug small airways and cause a lobular or multilobular atelectasis in the cranioventral regions of the lungs. The appearance can be quite similar grossly, though not microscopically, to that of *Mycoplasma pneumoniae*. Fatal cases have severe alveolar and interstitial pulmonary edema. Microscopically the lesions in uncomplicated cases are typical of a virus-induced, necrotizing bronchitis-bronchiolitis, which in severe cases extends into the alveoli as bronchointerstitial pneumonia. It is characterized by thickening and infiltration of the alveolar wall with mononuclear cells, and aggregates of macrophages, neutrophils, mucus, and some necrotic cells within the alveolar lumen. If these changes are extensive enough, the lumen of bronchioles can be occluded by exudate, causing lobular atelectasis. Viral antigen can be demonstrated in infected epithelial cells by immunoperoxidase techniques. In the later stages of alveolar inflammation, neutrophils are progressively replaced by intraalveolar macrophages, unless the pneumonia is complicated by secondary bacterial infections. Recent serologic surveys indicate that infection is also prevalent in wild pigs.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Clinically a sudden onset of painful and often paroxysmal coughing is followed by respiratory distress, nasal discharge, high fever, stiffness, and weakness or even prostration in most or the entire herd, including animals of all age groups. The outbreak subsides virtually without mortality within a week; the clinical appearance is much more alarming than the pathologic changes, unless the pigs have secondary infection with bacteria. Infection can be confirmed using PCR in secretions collected with nasal swabs. The most important effect of most outbreaks of influenza is severe weight loss, but pregnant sows also abort or give birth to weak piglets.

9.2.3.9.4.2

### Porcine reproductive and respiratory syndrome (PRRS)

A novel disease named “mystery disease of swine” was first recognized in the United States in 1987. In 1990 it was also seen in Europe, and since then the disease has been reported in many Latin American and Asian countries. In 1991 Dutch investigators isolated a virus as the etiologic agent, which is currently classified under the *Arterivirus* group.

535

536

As its name implies, porcine reproductive and respiratory syndrome is characterized by late-term abortions and stillbirths and respiratory problems in young pigs. The respiratory form generally seen in nursing or young pigs is clinically characterized by anorexia, dyspnea, cough, and occasional death. Some piglets develop severe cyanosis of the abdomen and ears, which explains why this syndrome when first described in Europe was named “blue ear disease.” The pathogenesis has not been completely elucidated, but it is presumed that there is a mucosal portal of entry with virus replication in local macrophages, followed by transient viremia and finally dissemination of phagocytic cells to the lungs and other organs, such as the thymus, liver (Kupffer cells), spleen, all lymph nodes, and intestine. The PRRS virus is known to induce apoptosis as a mechanism of cell destruction and persistent infection as a mechanism of dissemination. Although clinical evidence suggests that the PRRS virus also inhibits pulmonary defense mechanisms, experimental studies have been inconsistent in producing dual infections with other, secondary pathogens. Detection of porcine parvovirus and circovirus in pigs with PRRS has created controversy regarding the pathogenesis of this disease (see Postweaning Multisystemic Wasting Syndrome).

On postmortem examination, pulmonary lesions vary from very mild changes characterized by failure of the lung to collapse when the thorax is opened and the presence of rib imprints (Fig. 9-52) to severe changes manifested by consolidation of the lung in cases that have been complicated with bacterial pneumonia. Tracheobronchial and mediastinal lymph nodes are enlarged. Microscopically, pulmonary changes are those of interstitial pneumonia characterized by thickening of alveolar walls by infiltrating macrophages and lymphocytes and mild hyperplasia of type II pneumonocytes. Necrotic cells are scattered in the alveolar lumens. Unlike some other viral infections, bronchiolar epithelium appears not to be affected. Diagnosis of PRRS in tissue collected at the postmortem room can be confirmed by immunohistochemistry and PCR techniques. Infected pigs may become carriers and transmit the infection through body fluids and semen.

9.2.3.9.4.3

### Postweaning multisystemic wasting syndrome (PMWS)

Another newly recognized porcine syndrome, characterized clinically by progressive emaciation in weaned pigs, has been recently described in Canada, the United States, and Europe. Because of the clinical signs and lesions in many organs, this syndrome was named postweaning multisystemic

## Pathologic Basis of Veterinary Disease, 4th Edition

wasting syndrome (PMWS); a porcine circovirus-2 (PCV-2) has been incriminated as the etiologic agent.

At necropsy, affected pigs are in poor body condition, and the most remarkable changes, not considering other possible secondary infections, are enlargement of the superficial and visceral lymph nodes and a mild interstitial pneumonia characterized by failure of the lungs to collapse when the thorax is opened. Jaundice is occasionally observed. Microscopically the lymph nodes show necrosis of lymphoid follicles, depletion of lymphocytes, and notable proliferation of follicular macrophages, some of which fuse and form syncytial cells (granulomatous lymphadenitis). In many cases, large basophilic inclusion bodies resembling grapes are often present in the cytoplasm of macrophages, particularly in Peyer's patches, spleen, and lymph nodes. The lungs show thickening of the alveolar walls because of hyperplasia of type II pneumonocytes and interstitial infiltrates of mononuclear cells, some of which may contain intracytoplasmic inclusion bodies. Circovirus antigen can be confirmed in affected tissue by immunohistochemical or PCR techniques.

Secondary infections with *Pneumocystis carinii* are commonly seen in pigs with PRRS and PMWS. Characteristically, alveoli are filled with a distinctive foamy exudate, which contains the organism not visible in H&E stain but easily demonstrated with Gomori's methenamine silver stain (Fig. 9-73). In human beings, *Pneumocystis carinii* pneumonia (pneumocystosis) is one of the most common and often fatal complications in AIDS patients. As in AIDS patients, in foals and pigs, abnormal populations of CD4<sup>+</sup> and CD8<sup>+</sup> T lymphocytes have been incriminated as the underlying mechanism leading to pneumocystosis.

536

537

**Fig. 9-73 Pneumocystosis (*Pneumocystis carinii*), lung, pig.** Alveoli are filled with a foamy eosinophilic proteinaceous material in which numerous punctiform organisms (*arrows*) are present. *Inset:* Silver stained oval bodies typical of *Pneumocystis carinii*. Pneumocystosis is generally a microscopic diagnosis because this condition does not cause remarkable gross lesions. Gomori's methenamine silver stain. (**Figure and Inset**, Courtesy Dr. A. López, Atlantic Veterinary College.)

9.2.3.9.4.4

### Porcine enzootic pneumonia (mycoplasmal pneumonia of pigs)

This highly contagious disease of pigs caused by *Mycoplasma hyopneumoniae* is grossly characterized by suppurative or catarrhal bronchopneumonia (Fig. 9-74). When its worldwide prevalence and deleterious effect on feed conversion are taken into account, this disease is probably the most economically significant respiratory disease of pigs. Although an infectious disease, it is very much influenced by immune status and management factors, such as crowding (airspace and floor space), ventilation (air exchange rate), concentrations of noxious gases in the air (ammonia, hydrogen sulfide), relative humidity, temperature fluctuations, and mixing of stock from various sources. It has been recently demonstrated with PCR technique that *Mycoplasma hyopneumoniae* is present in the air of infected farms.

Fig. 9-74 **Chronic suppurative bronchopneumonia (enzootic pneumonia), lung, pig.** **A**, Cranioventral consolidation of 40% to 50% of pulmonary parenchyma. Consolidated lung (**C**) is firm, and the outlines of the lobules are accentuated by edema of the interlobular septa. **N**, Normal lung. **B**, The bronchiole and alveoli contain numerous neutrophils and macrophages. Some of the neutrophils are migrating from the capillaries of the lamina propria of the bronchiole into its lumen. Alveoli are edematous and contain similar inflammatory cells. Alveolar septa are also widened by inflammation. *Inset*: Higher magnification of wall of bronchiole [Fig. 9-74, B](#). H&E stain. (**A**, Courtesy Ontario Veterinary College. **B** and *Inset*, Courtesy Dr. A. López, Atlantic Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

The cause of porcine enzootic pneumonia remained unclear for many years, and so the disease was mistakenly known as “virus pneumonia of pigs” based on the assumption that if the agent was hard to find it must be a virus. The causative agent, *Mycoplasma hyopneumoniae*, is a fastidious organism and very difficult to grow; thus the final diagnosis is frequently based on interpretation of lesions alone, or supported by ancillary tests to detect this mycoplasma in affected lungs by immunohistochemical, immunofluorescence, enzyme-linked immunosorbent assay (ELISA), or PCR techniques. The bronchopneumonic lesions of porcine enzootic pneumonia are in most cases mild to moderate, and thus mortality is low unless complicated with secondary pathogens, such as *Pasteurella multocida*, *Arcanobacterium pyogenes*, *Bordetella bronchiseptica*, *Haemophilus* spp., *Mycoplasma hyorhinis*, and other mycoplasmas and ureaplasmas. Although the pathogenesis of porcine enzootic pneumonia is not completely elucidated, it is known that *Mycoplasma hyopneumoniae* first adheres to the cilia of the bronchi by means of a unique adhesive protein, produces ciliostasis, and finally colonizes the respiratory system by firmly attaching to the ciliated epithelial cells of the trachea and the bronchi of the cranioventral regions of the lungs. Once attached to the respiratory epithelium, it provokes an influx of neutrophils into the tracheobronchial mucosa, causes extensive loss of cilia (deciliation), stimulates an intense hyperplasia of lymphocytes in the BALT, and attracts mononuclear cells into the peribronchial, bronchiolar, and alveolar interstitium. Additional virulence factors include the ability of *Mycoplasma hyopneumoniae* to reduce the phagocytic activity of neutrophils in the lung and change the chemical composition of mucus, predisposing the lung to secondary bacterial infections.

The lesions caused by *Mycoplasma hyopneumoniae* start as a bronchointerstitial pneumonia microscopically characterized by mononuclear infiltrates in the alveolar walls and a few macrophages and neutrophils in bronchiolar and alveolar lumens. This inflammatory reaction progresses to a suppurative or mucopurulent bronchopneumonia once secondary pathogens, such as *Pasteurella multocida*, *Bordetella bronchiseptica*, or *Arcanobacterium pyogenes*, are involved (commonly seen at necropsy). In most pigs, gross lesions affect only portions of the cranial and accessory lobe, but in more severely affected pigs, lesions involve 50% or more of the cranioventral portions of the lungs (Fig. 9-74). The affected lungs are dark red in the early stages and have a homogeneous pale-gray (“fish flesh”) appearance in the more chronic stages of the disease. On the cut surface, exudate can easily be expressed from airways, and depending on the stage of the lesions and secondary infections, the exudate varies from purulent to mucopurulent to mucoid. Microscopic lesions are characterized by an influx of macrophages and neutrophils into the bronchi, bronchioles, and alveoli with notable BALT hyperplasia. In some cases, accumulation of exudate can be severe enough to cause occlusion of bronchioles and atelectasis of their lobules (Fig. 9-74). The suppurative bronchopneumonia may be accompanied by a mild fibrinous pleuritis, which is often more severe if other organisms, such as *Mycoplasma hyorhinis*, *Pasteurella multocida*, or *Actinobacillus pleuropneumoniae*, are also involved. Abscesses and pleural fibrous adhesions can be long-term sequelae of chronic complicated infections.

Clinically, enzootic pneumonia occurs as a herd problem in two disease forms. A newly acquired infection of a previously clean herd causes disease in all age groups, resulting in acute respiratory distress and low mortality. In a chronically infected herd, the mature animals are immune, and clinical signs are usually apparent only in growing pigs at times of particular stress, such as at weaning. In such herds, coughing and reduced rate of weight gain are the most notable signs.

9.2.3.9.4.5

### Porcine pasteurellosis

This infectious disease complex with unclear pathogenesis includes primary infections caused by *Pasteurella multocida* alone, or more frequently, as a secondary infection when the opportunistic

## Pathologic Basis of Veterinary Disease, 4th Edition

bacterium colonizes the lung only after the defense mechanisms are impaired (porcine pneumonic pasteurellosis). In some rare cases, *Pasteurella multocida* causes acutely fatal septicemias in pigs. It is important to remember that *Pasteurella multocida* serotypes A and D are both part of the normal nasal flora and are also causative agents of bronchopneumonia in pigs.

*Pasteurella multocida* is a secondary pathogen frequently isolated from the lungs of pigs with porcine influenza, PRRS, porcine circovirus-2 infection, pseudorabies, classical swine fever (hog cholera), enzootic pneumonia, and porcine pleuropneumonia. Secondary infections with *Pasteurella multocida* notably change the early and mild bronchointerstitial reaction of enzootic and viral pneumonias into a severe suppurative bronchopneumonia with multiple abscesses and sometimes pleuritis. The other important role for *Pasteurella multocida* in porcine pneumonias is as a cause of a fulminating, cranioventral, fibrinous bronchopneumonia (pleuropneumonia) following influenza virus infection or stress associated with poor management practices, such as faulty ventilation with high levels of ammonia in the air. The nature of the lesion and the predisposing factors of poor management or coexisting viral infections suggest that fulminating porcine pasteurellosis has a pathogenesis similar to that of pneumonic manheimiosis of cattle. Pharyngitis with subcutaneous cervical edema, fibrinohemorrhagic polyarthritis, and focal lymphocytic interstitial nephritis are also associated with porcine pneumonic pasteurellosis. Whether this disease is a separate form of pasteurellosis (septicemic) or a change to bronchopneumonia needs to be elucidated. Sequelae of porcine pneumonic pasteurellosis include fibrous pleuritis and pericarditis, pulmonary abscesses, so-called sequestra, and usually death. In contrast to responses in ruminants, *Mannheimia haemolytica* is not a respiratory pathogen for pigs, but in some instances it can cause abortion in sows.

### 9.2.3.9.4.6

#### Porcine pleuropneumonia

This entity is a highly contagious, worldwide disease of pigs, caused by *Actinobacillus pleuropneumoniae* (*Haemophilus pleuropneumoniae*), which is characterized by a severe, often fatal, fibrinous bronchopneumonia with extensive pleuritis (pleuropneumonia). Survivors generally develop notable residual lesions and become carriers of the organisms. Porcine pleuropneumonia is an increasingly important cause of acute and chronic pneumonias, particularly in intensively raised pigs (2 to 5 months old). Transmission of *Actinobacillus pleuropneumoniae* occurs by the respiratory route, and the disease can be reproduced experimentally by intranasal inoculation of the bacterium. Considered as a primary pathogen, *Actinobacillus pleuropneumoniae* can sporadically produce septicemia in young pigs and otitis media and otitis interna with vestibular syndrome in weaned pigs. Twelve serotypes of the organism, most of which can cause the disease, have been identified. The pathogenesis is not yet well understood, but specific virulence factors, such as capsular factors, fimbriae and adhesins, lipopolysaccharide, hemolysins, cytotoxins, and permeability factors have been identified. These factors allow *Actinobacillus pleuropneumoniae* to attach to cells; produce pores in cell membranes; damage capillaries and alveolar walls, resulting in vascular leakage and thrombosis; impair phagocytic function; and elicit failure of clearance mechanisms.

The gross lesions in the acute form consist of a fibrinous bronchopneumonia characterized by severe consolidation and a fibrinous exudate on the pleural surface. Although all lobes can be affected, a common site is the dorsal area of the caudal lobes. In fact, a large area of fibrinous pleuropneumonia involving the caudal lobe of a pig's lung is considered almost diagnostic for this disease (Fig. 9-75). On the cut surface, consolidated lungs have notably dilated interlobular septa and irregular, but well-circumscribed areas of coagulative necrosis caused by potent cytotoxins produced by *Actinobacillus pleuropneumoniae*. Except for the distribution, pulmonary lesions of porcine

538

539

## **Pathologic Basis of Veterinary Disease, 4th Edition**

---

pleuropneumonia are identical to those of pneumonic manheimiosis of cattle. The microscopic lesions are also very similar to those of bovine pneumonic manheimiosis and include areas of necrosis surrounded by a thick cluster of “streaming (oat-shaped) leukocytes,” and a notable distention of the interlobular septa because of severe edema and lymph vessel thrombosis. Pigs with the chronic form have multiple pulmonary abscesses and large pieces of necrotic lung encapsulated by connective tissue (sequestra), changes frequently seen in slaughter houses.

**Fig. 9-75 Porcine pleuropneumonia (*Actinobacillus pleuropneumoniae*), lung, pig.** **A**, In peracute porcine pleuropneumonia the pneumonic lesions are locally extensive in the dorsal aspects of the caudal lung lobes. There is lobular congestion, consolidation, and interlobular edema. **B**, As the disease progresses and becomes acute to subacute, the lesions expand in size and severity. Note the large area of hemorrhagic necrotizing fibrinous bronchopneumonia. Fibrin is abundant (*arrow*) on the pleural surface and in interlobular septa. **C**, The cut surface has numerous discrete and coalescing zones of lobular inflammation and necrosis (*upper left*), which are pale pink to white and often surrounded by a white margin (inflammation). There is extensive congestion (active hyperemia) and hemorrhage throughout the section. **D**, Alveoli are filled with fibrin, edema fluid, and neutrophils. Capillaries in alveolar septa are congested (active hyperemia), and in many cases there is necrosis of alveolar septa (not visible at this magnification). (**A**, Courtesy Dr. A. López, Atlantic Veterinary College. **B**, Courtesy Dr. J. Render, College of Veterinary Medicine and Animal Health Diagnostic Laboratory, Michigan State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **C** and **D**, Courtesy Dr. A.R. Doster, University of Nebraska; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Clinically, porcine pleuropneumonia can vary from an acute form with unexpected death and blood-stained froth at the nostrils and mouth to a subacute form characterized by coughing and dyspnea accompanied by clinical signs of sepsis such as high fever, hypoxemia, anorexia, and lethargy. A chronic form is characterized by decreased growth rate and persistent cough. Animals that survive often carry the organism in the tonsils, shed the organism, and infect susceptible pigs.

539

9.2.3.9.4.7

### *Haemophilus pneumonia*

540

In addition to Glasser's disease characterized by polyserositis (pericarditis, pleuritis, peritonitis, polyarthritis and meningitis), some serotypes of *Haemophilus parasuis* (originally *Haemophilus parasuis suis*) can also cause suppurative bronchopneumonia that, in some severe cases, can be fatal. The causal organism, *Haemophilus parasuis*, is usually carried in the nasopharynx of normal pigs and requires abnormal circumstances such as those following stress (weaning, cold weather) or viral infections (swine influenza or porcine circovirus-2). Specific pathogen-free (SPF) pigs seem to be particularly susceptible to Glasser's disease (arthritis and serositis) but not to pulmonary infection (bronchopneumonia).

9.2.3.9.4.8

### *Streptococcal pneumonia*

*Streptococcus suis* type II is a common cause of porcine disease worldwide and a serious zoonosis capable of causing death by septic shock or meningitis and residual deafness in butchers, veterinarians, and pig farmers. Typically, *Streptococcus suis* type II gains entrance to the susceptible young pig through the oropharyngeal mucosa and it can be carried in the tonsils, nasal mucosa, and mandibular lymph nodes of healthy animals, particularly in survivors of an outbreak. Infected sows can abort or vertically transmit the infections to their offspring. Some serotypes of *Streptococcus suis* cause neonatal septicemia, and this can result in suppurative meningitis, arthritis, polyserositis, myocarditis, valvular endocarditis, and embolic pneumonia. Other serotypes may reach the lung by the aerogenous route and cause suppurative bronchopneumonia, generally in combination with *Pasteurella multocida*, *Escherichia coli*, or *Mycoplasma hyopneumoniae*, and fibrinous bronchopneumonia when *Streptococcus suis* infection occurs in combination with *Actinobacillus pleuropneumoniae*.

9.2.3.9.4.9

### *Tuberculosis*

Tuberculosis is an important disease in pigs, which, in many countries, including those in North America, has a much greater prevalence in pigs than in cattle or other domestic mammals. Porcine tuberculosis is attributed to infection with *Mycobacterium bovis* and *Mycobacterium avium-intracellulare* complex. A common scenario in small mixed-farming operations is the diagnosis of avian tuberculosis at the time that pigs are slaughtered, the source being ingestion of tuberculous chickens or contaminated litter. As would be expected, granulomas are found in the mesenteric, mandibular, and retropharyngeal lymph nodes, and to a lesser extent in the intestine, liver, and spleen, and only in rare cases in the lung. The route of infection in pulmonary tuberculosis of pigs is most often hematogenous after oral exposure and intestinal infection. The microscopic lesions are basically those of tubercles, but the degree of encapsulation, caseation, and calcification varies with the type of mycobacterium, age of the lesion, and host immune response.

9.2.3.9.4.10

### Other infectious pneumonias of pigs

Porcine respiratory coronavirus (PRCV) is sporadically incriminated in pneumonia in pigs. This viral pneumonia is generally mild, and most pigs fully recover if the pneumonia is not complicated with other infections. Lesions in the lung are those of bronchointerstitial pneumonia with necrotizing bronchiolitis. Interestingly, infections with porcine and other respiratory coronaviruses have been used to investigate the pathogenesis of severe acute respiratory syndrome (SARS), an emerging and highly contagious condition recently reported in human beings and attributed to a novel human coronavirus (SARS-CoV). The relationship between SARS and animal coronavirus is still under investigation.

Septicemias in pigs often cause petechial hemorrhages in the lung and pulmonary edema, and these features may be a part of African swine fever, classical swine fever (hog cholera), pseudorabies, and other diseases. *Salmonellae*, *Escherichia coli*, and *Listeria monocytogenes* can cause severe interstitial pneumonia as part of a septicemic process in very young animals. *Salmonella choleraesuis* causes a necrotizing fibrinous pneumonia, and *Salmonella typhisuis*, a chronic suppurative bronchopneumonia.

Foreign body granulomatous pneumonia occurs frequently in pigs following inhalation of vegetable material (starch pneumonia), presumably from dusty (nonpelleted) feed. Lesions are clinically silent but are often mistaken for other pneumonic processes during inspection at slaughter houses. Microscopically, pulmonary changes are typical of foreign body granulomatous inflammation in which variably sized feed particles are surrounded by macrophages and neutrophils, and often are found in multinucleated giant cells. Feed (vegetable) particles appear as thick-walled polygonal cells that stain positive with PAS because of their rich carbohydrate (starch) content.

9.2.3.9.4.11

### Parasitic pneumonias of pigs

*Metastrongylus apri* (*elongatus*), *Metastrongylus salmi*, and *Metastrongylus pudendotectus* (lungworms) of domestic and feral pigs occur throughout most of the world and require earthworms as intermediate hosts for transmission. Lungworms may transmit the virus of swine influenza. The importance of pig lungworms is mainly because of growth retardation of the host. Clinical signs include coughing because of parasitic bronchitis.

The gross lesions, when noticeable, consist of small gray nodules, particularly along the ventral borders of the caudal lobes. The adult worms are grossly visible in bronchi, and microscopically, the parasites cause a catarrhal inflammation with infiltration of eosinophils and lobular atelectasis ([Fig. 9-76](#)).

540

541

Fig. 9-76 **Acute verminous bronchitis (*Metastrongylus apri*), bronchus, cross section, pig.** Several sections of nematodes (*Metastrongylus apri*) admixed with mucus, neutrophils, and eosinophils (not visible at this magnification) are present in the lumen of the bronchus. H&E stain. (Courtesy Armed Forces Institute of Pathology and Dr. G. Conboy, Atlantic Veterinary College.)

During migration through the lungs of pigs, larvae of *Ascaris suum* can cause edema, focal subpleural hemorrhages, and interstitial inflammation (Fig. 9-54). Hemorrhages also occur in the liver, and after fibrosis they become the large, white “milk spots” seen so frequently as incidental findings at necropsy. It has recently been reported that *Ascaris suum* may cause immunosuppression in severely affected pigs.

### 9.2.3.9.5

#### Pneumonias of Dogs

In general, inflammatory diseases of the lungs are less of a problem in dogs than in food-producing species and can be subdivided in two major groups, infectious and noninfectious pneumonias. Of the infectious causes, two account for most cases: infectious tracheobronchitis (kennel cough), which was discussed previously, and canine distemper. Uremia and paraquat toxicity are perhaps the two most notable noninfectious causes of pulmonary disease in dogs.

### 9.2.3.9.5.1

#### Canine distemper

Canine distemper is an important and ubiquitous infectious disease of dogs, other Canidae, wild Felidae, Mustelidae, and marine mammals around the world. It is caused by a morbillivirus that is antigenically related to the human measles, rinderpest, and “peste de petit ruminants” viruses. Distemper virus invades through the upper respiratory tract and conjunctiva, proliferates in regional lymph nodes, becomes viremic, and, in dogs with an inadequate antibody response, infects nearly all body tissues (pantropic), particularly the epithelial cells. During viremia, distemper virus hampers the

## Pathologic Basis of Veterinary Disease, 4th Edition

immune response and appears to down-regulate cytokine production. This virus can target the lungs either directly as a viral pneumonia or by its immunosuppressive effects rendering the lungs susceptible to secondary bacterial infections.

Gross lesions in the acute stages include serous to catarrhal to mucopurulent nasopharyngitis and conjunctivitis. The lungs are edematous and have a diffuse interstitial pneumonia (Fig. 9-77) microscopically characterized by necrotizing bronchiolitis, necrosis and exfoliation of pneumonocytes, mild alveolar edema, and several hours later, thickening of the alveolar walls because of interstitial mononuclear cell infiltrates and hyperplasia of type II pneumonocytes. Secondary infections with *Bordetella bronchiseptica* and mycoplasmas are common and induce life-threatening suppurative bronchopneumonia. The thymus may be small relative to the age of the animal because of viral-induced lympholysis.

Microscopically, eosinophilic inclusions are present in the epithelial cells of many tissues, in the nuclei or cytoplasm, or in both (Fig. 9-77). They appear early in the bronchiolar epithelium, but are most prominent in the epithelium of the lung, stomach, renal pelvis, and urinary bladder, making these tissues good choices for diagnostic examination. The suppurative secondary bronchopneumonias often hinder the detection of viral lesions in the lung, particularly because bronchiolar cells containing inclusion bodies exfoliate and mix with the neutrophils recruited by the bacterial infection. Distemper virus antigens can be readily demonstrated in infected cells by the immunoperoxidase technique (Fig. 9-77). This technique can also be used in skin biopsies for the antemortem diagnosis of canine distemper.

541

542

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Distemper virus also has a tendency to affect developing tooth buds and ameloblasts, causing enamel hypoplasia in dogs that recover from infection. Of all distemper lesions, demyelinating encephalomyelitis, which develops late, is the most devastating (see [Chapter 14](#)). Sequelae to distemper include the nervous and pneumonic complications mentioned previously and such various systemic infections as toxoplasmosis and sarcocystosis because of depressed immunity. Persistent viral infection occurs in some animals that survive the disease.

Clinical signs consist of biphasic fever, diarrhea, vomiting, weight loss, mucopurulent oculonasal discharge, coughing, respiratory distress, and possible loss of vision. Weeks later, hyperkeratosis of foot pads (“hard pad”) and the nose are observed, along with nervous signs including ataxia, paralysis, convulsions, or residual myoclonus (muscle twitches, tremors, and “tics”). Distemper virus is transmitted to susceptible puppies through infected body fluids.

9.2.3.9.5.2

### Canine adenovirus type 2 (CAV-2) infection

This entity is a common, but transient contagious disease of the respiratory tract of dogs, causing mild fever, oculonasal discharge, coughing, and poor weight gain. The portal of entry is generally by inhalation of infected aerosols followed by viral replication in pneumonocytes. Pulmonary lesions are initially those of a bronchointerstitial pneumonia, with necrosis and exfoliation of bronchiolar and alveolar epithelium and edema, and a few days later, proliferation of type II pneumonocytes, mild infiltration of neutrophils and lymphocytes in alveolar interstitium, and hyperplastic bronchitis and bronchiolitis. Large basophilic intranuclear viral inclusions are typically seen in bronchiolar and alveolar epithelial cells. The disease is sometimes associated or may be confused with the infectious tracheobronchitis complex (kennel cough). The infection with canine adenovirus is clinically mild unless complicated with a secondary bacterial infection. Experimental work suggests CAV-2 reinfection may lead to hyperreactive airways. However, it is not clear if this outcome is true in natural infections.

9.2.3.9.5.3

### Canine herpesvirus 1 (CHV-1)

This viral infection can cause fatal generalized disease in newborn puppies, and it is probably part of the variety of factors that result in the “fading puppy syndrome.” Hypothermia has been suggested as a pivotal component in the pathogenesis of fatal infections in puppies. CHV-1 also causes necrotizing rhinotracheitis and secondary bronchopneumonia in older animals. Many dogs are seropositive, suggesting that transient or subclinical infections are more common than realized; the virus remains latent in ganglia and can be reactivated following stress, resulting in asymptomatic transmission of CHV-1 virus to offspring via the placenta, resulting in abortion or stillbirths.

9.2.3.9.5.4

### Canine influenza (canine flu)

Canine influenza is an emerging contagious respiratory infection of dogs that has been recently described in the United States. It has a high morbidity (close to 100%), but the mortality, as with most other influenza infections, is relatively low (less than 8%). The disease is caused by a novel influenza-A virus that appears to be a mutation from a previously recognized strain of equine influenza virus, presumably the H3N8 strain, and is clinically manifested by severe cough. It must be distinguished from kennel cough. Pulmonary lesions are generally mild and transient, but infected dogs are susceptible to secondary bacterial bronchopneumonia. The most relevant lesions in dogs dying

## Pathologic Basis of Veterinary Disease, 4th Edition

---

unexpectedly from canine influenza are pleural and pulmonary hemorrhages. Microscopically, there is necrotizing bronchitis and bronchiolitis with exudation of neutrophils and macrophages. Influenza antigen can be demonstrated by immunohistochemistry in airway epithelium and alveolar macrophages.

9.2.3.9.5.5

### Bacterial pneumonias of dogs

Dogs generally have bacterial pneumonias when the pulmonary defense mechanisms have been impaired. *Pasteurella multocida*, *Streptococcus* spp., *Escherichia coli*, *Klebsiella pneumoniae*, and *Bordetella bronchiseptica* can be involved in pneumonia secondary to distemper or after aspiration of gastric contents (Fig. 9-78). *Streptococcus zooepidemicus* also causes acute and fatal hemorrhagic pleuropneumonia with hemorrhagic pleural effusion in dogs. Death is generally a consequence of severe sepsis or generalized bacterial embolisms affecting the lungs, liver, brain, and lymph nodes. The primary source of the infection cannot be determined in most cases. Dental disease in dogs may be a source of systemic and pulmonary infection, which is not a new concept, as it has recognized in human medicine for many years. The role of mycoplasmas in canine pneumonia is still uncertain, as these organisms are frequently isolated from normal nasopharyngeal flora.

Tuberculosis is uncommon in dogs, as these animals appear to be quite resistant to infection; most cases occur in immunocompromised dogs or in dogs living with infected human beings. Dogs are susceptible to the *Mycobacterium tuberculosis*, *Mycobacterium bovis*, and *Mycobacterium avium* complex strains, and therefore canine infection presupposes contact with human or animal tuberculosis.

542

543

The clinicopathologic manifestation is pulmonary after inhalation or alimentary after oral exposure, but in most cases infection is disseminated to lymph nodes and visceral organs. The gross pulmonary lesions are multifocal, firm, usually calcified nodules with necrotic centers, most often seen in the lungs, lymph nodes, kidneys, and liver. Diffuse granulomatous pleuritis and pericarditis with copious serofibrinous or sanguineous effusion are common. Microscopically, granulomas are formed by closely packed macrophages, but with very little connective tissue.

**Fig. 9-78 Aspiration pneumonia, bronchopneumonia, right lung, dog.**

The cranioventral portions of the lung are firm and contain purulent exudate (*yellow areas*). Aspiration pneumonia starts as an acute necrotizing bronchitis and bronchiolitis caused by aspiration of irritant materials such as gastric acid or a caustic material administered by mouth. The aspirate also contains potentially pathogenic bacteria, and because the mucociliary apparatus is damaged and these bacteria are not removed, they settle into the ventral portions of the lung (from gravity) and provoke a fibrinosuppurative bronchopneumonia. (*Courtesy Dr. A. López, Atlantic Veterinary College.*)

9.2.3.9.5.6

### Mycotic pneumonias of dogs

These are serious diseases seen commonly in animals in some areas. There are two main types: those caused by opportunistic fungi and those caused by a group of fungi associated with systemic “deep” mycoses. All these fungi affect human beings and most domestic animals but are probably not transmitted between species.

Opportunistic fungi, such as *Aspergillus fumigatus*, are important in birds, but in domestic animals they mainly affect immunosuppressed animals or those animals on prolonged antibiotic therapy. The pulmonary lesion is a multifocal, nodular, pyogranulomatous, or granulomatous pneumonia. Microscopically, the fungal hyphae are present, and there is usually necrosis, vasculitis, neutrophilic

## Pathologic Basis of Veterinary Disease, 4th Edition

---

infiltrates, macrophages and lymphocytes, and fibroblasts, eventually leading to encapsulation of the granulomas.

Systemic (deep) mycoses are caused by *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Coccidioides immitis*, and *Cryptococcus neoformans* (Fig. 9-79). Blastomycosis mainly affects dogs and is discussed here, whereas cryptococcosis is discussed in the section Pneumonias of Cats. In contrast to other fungi such as *Aspergillus* spp., organisms of the systemic mycosis group are all primary pathogens of human beings and animals and thus do not necessarily require a preceding immunosuppression to cause disease. These fungi have virulence factors that favor hematogenous dissemination and evasion of immune and phagocytic responses. In general, cytological evaluation of affected tissues is very rewarding in the antemortem diagnosis of all systemic mycoses. Systemic dissemination is often exacerbated by the administration of immunosuppressant drugs such as corticosteroids.

Blastomycosis occurs in many countries of the American continent, Africa, and the Middle East and occasionally in Europe. In the United States, it is most prevalent in the Atlantic, St. Lawrence, and Ohio-Mississippi River Valley states, as compared with the Mountain-Pacific region. *Blastomyces dermatitidis* is a dimorphic fungus (mycelia-yeast) seen mainly in young dogs and occasionally in cats. This fungus is present in the soil, and inhalation of spores is considered the principal route of infection; thus it most frequently affects outdoor and hunting dogs. From the lung, infection is disseminated hematogenously to other organs, mainly bone, skin, brain, and probable eyes.

Pulmonary lesions are characterized by multifocal to coalescing granulomatous pneumonia, generally with firm nodules (pyogranulomas) scattered throughout the lungs (Fig. 9-80). Microscopically, nodules are granulomas with numerous macrophages (epithelioid cells), some neutrophils, multinucleated giant cells, and thick-walled yeasts (Figs. 9-79, A and 9-80). Yeasts are 5 to 25  $\mu\text{m}$  in diameter and are much better visualized when they are stained with PAS reaction or Gomori's methenamine silver stain. Nodules can also be present in other tissues, chiefly lymph nodes, skin, spleen, liver, kidneys, bones, testes, prostate, and eyes. This fungus can be easily identified in properly prepared and stained transtracheal washes or lymph node aspirates.

Clinical signs can reflect involvement of virtually any body tissue; pulmonary effects include cough, decreased exercise tolerance, and terminal respiratory distress.

---

Coccidioidomycosis (San Joaquin Valley fever), caused by the dimorphic fungus <i>Coccidioides immitis</i> ,	543
occurs mainly in animals living in arid regions of the southwestern United States, Mexico, and Central and South America. It is a primary respiratory tract (aerogenous) infection commonly seen at slaughterhouses in clinically normal feedlot cattle. In dogs, coccidioidomycosis also has an aerogenous portal of entry and then disseminates systemically to other organs. Clinical signs relate to the location of lesions, so there can be respiratory distress, lameness, generalized lymphadenopathy, or cutaneous lesions, among others.	544

---

Fig. 9-79 **Systemic (deep) mycoses.** **A**, *Blastomyces dermatitidis*, 8 to 25  $\mu\text{m}$  in diameter, broad-based budding spherical yeastlike organisms, intracellular or extracellular location. H&E stain. **B**, *Cryptococcus neoformans*, spherical, 2 to 10  $\mu\text{m}$  in diameter, usually surrounded by a thick mucus capsule, which can increase the overall diameter up to 30  $\mu\text{m}$ , intracellular or extracellular location. The mucus capsule does not stain with H&E (*inset*) but is stained by mucicarmine. With routine mountants, the capsule shrinks and distorts, but this effect has been prevented here by using an aqueous mounting medium. Mayer's mucicarmine stain, aqueous mounting medium. *Inset*: In H&E stained sections, the capsule is not visible but appears as a halo around the cell body. H&E stain. **C**, *Histoplasma capsulatum*, located intracellularly, is spherical to slightly elongated, 5 to 6  $\mu\text{m}$  in diameter. H&E stain. **D**, *Coccidioides immitis*, spherules, 20 to 30  $\mu\text{m}$  in diameter, containing endospores (<5  $\mu\text{m}$  in diameter), intracellular or extracellular location. H&E stain. The lesions caused by *Coccidioides immitis* consist of focal granulomas or pyogranulomas that can have suppurative or caseated centers. The fungal organisms are readily seen in histologic or cytologic

## Pathologic Basis of Veterinary Disease, 4th Edition

preparation as large (10 to 80  $\mu\text{m}$  in diameter), double-walled and highly refractile spherules (Fig. 9-79, D).

Histoplasmosis is a systemic infection that results from inhalation of another dimorphic fungus, *Histoplasma capsulatum*. Histoplasmosis occurs sporadically in dogs and human beings, and to a lesser extent, in cats and horses. Bats often eliminate *Histoplasma capsulatum* in the feces, and droppings from bats and birds heavily promote the growth and survival of this fungus in the soil of enzootic areas.

Pulmonary lesions are grossly characterized by variably sized, firm, well-encapsulated granulomas,

544

and, sometimes, more diffuse involvement of the lungs. Microscopically, granulomatous tissue typically has many macrophages filled with small (1 to 3  $\mu\text{m}$ ), punctiform, intracytoplasmic, dark oval bodies (yeasts), and best demonstrated with PAS reaction (Fig. 9-79, C) or Gomori's methenamine silver stain. Similar nodules can be present in other tissues, chiefly lymph nodes, spleen, intestines, and liver.

545

## Pathologic Basis of Veterinary Disease, 4th Edition

9.2.3.9.5.7

### Aspiration pneumonia in dogs

This disease is an important form of pneumonia in dogs when vomited or regurgitated materials are aspirated into the lungs or when drugs or radiographic contrast media is accidentally introduced into the airways. As in other animal species, aspiration pneumonia may be unilateral or may more severely affect the right cranial lobe (Fig. 9-81). The severity of lesions depends very much on the chemical and microbiologic composition of the aspirated material. In general, aspiration in monogastric animals, particularly in dogs and cats, is more severe because of the low pH of the gastric contents (chemical pneumonitis). In severe cases, dogs and cats die rapidly from septic shock and ARDS, which is microscopically characterized by diffuse alveolar damage, protein-rich pulmonary edema, neutrophilic alveolitis, and formation of typical hyaline membranes along the alveolar walls (Fig. 9-81). In animals that survive the acute stages of aspiration, pulmonary lesions progress to bronchopneumonia. Aspiration pneumonia is a common sequela to cleft palate, and megaesophagus in dogs secondary to either myasthenia gravis or persistent right aortic arch. It is also an important complication of anesthesia.

9.2.3.9.5.8

### Toxic pneumonias in dogs

Paraquat, a broad-spectrum herbicide widely used in gardening and agriculture, can cause severe and often fatal toxic interstitial pneumonia (pneumonitis) in dogs, cats, human beings, and other species. Following ingestion or inhalation, this herbicide selectively accumulates in the lung and paraquat metabolites are produced by Clara cells. These metabolites promote local release of free radicals in the lung, which cause extensive injury to Clara cells and to the blood-air barrier, presumably through lipid peroxidation of type I and II pneumonocytes and alveolar endothelial cells. Paraquat toxicity has been used experimentally as a model of oxidant-induced alveolar injury and pulmonary fibrosis. Soon after poisoning, the lungs are heavy, edematous, and hemorrhagic because of extensive necrosis of epithelial and endothelial cells in the alveolar walls. The lungs of animals that survive acute paraquat toxicosis are pale, fail to collapse when the thorax is opened, and have interstitial emphysema, bullous emphysema, and pneumomediastinum. Microscopic findings in the acute and subacute phases include necrosis of type I pneumonocytes, interstitial and alveolar edema, intraalveolar hemorrhages, and proliferation of type II pneumonocytes. In the chronic stages (4 to 8 weeks later), the lesions are typically characterized by severe interstitial and intraalveolar fibrosis.

Uremic pneumonopathy (pneumonitis) is one of the many extrarenal lesions seen in dogs with chronic uremia. Lesions are characterized by a combination of pulmonary edema and calcification of vascular smooth muscle and alveolar basement membrane. In severe cases, alveolar calcification prevents lung collapse when the thorax is opened.

Grossly, the lungs appear diffusely distended, pink or red in color, and show a rough pleural surface with rib imprints (Fig. 9-31). On palpation, the pulmonary parenchyma has a typical “gritty” texture because of mineralization of the alveolar and vascular walls which is best visualized microscopically by using special stains such as von Kossa (Fig. 9-31). Because this is not primarily an inflammatory lesion, the term *pneumonitis* should be avoided.

545

546

**Fig. 9-81 Acute hemorrhagic bronchopneumonia, acute respiratory distress syndrome (ARDS), lungs, 4-week-old puppy.** **A**, Note that the lungs did not collapse when the thorax was opened (loss of negative pressure) and as a result fill almost the entire thoracic cavity. The cranioventral aspects of the lung are consolidated with diffuse hemorrhage. **B**, Alveolar capillary congestion, thick hyaline membranes along the alveolar septa (*arrows*), and intraalveolar hemorrhage. These microscopic changes are typical of the diffuse alveolar damage seen in lungs with ARDS. H&E stain. (**A and B**, Courtesy Dr. A. López, Atlantic Veterinary College.)

### 9.2.3.9.5.9

#### Parasitic pneumonias of dogs

Toxoplasmosis is a worldwide disease caused by the obligate intracellular, protozoal parasite *Toxoplasma gondii*. Cats and other Felidae are the definitive host where the mature parasite divides sexually in the intestinal mucosa. Human beings, dogs, cats, and many wild mammals can become intermediate hosts following accidental ingestion of fertile oocysts shed in cat feces, or fetuses can be infected transplacentally from an infected dam. In most instances, the parasite infects many cells of different tissues, induces an antibody response (seropositive animals), but does not cause clinical disease. Toxoplasmosis is often triggered by immunosuppression, such as that caused by canine distemper virus. Toxoplasmosis is characterized by focal necrosis of epithelial cells around the protozoan.

Pulmonary lesions are severe, multifocal necrotizing interstitial pneumonia with notable proliferation of type II pneumonocytes and infiltrates of macrophages and neutrophils. Other lesions in disseminated toxoplasmosis include focal necrotizing hepatitis, myocarditis, splenitis, myositis, encephalitis, and ophthalmitis. The parasites appear microscopically as small (3 to 6  $\mu\text{m}$ ) basophilic cysts that can be found free in affected tissues or within the cytoplasm of many epithelial cells and macrophages. Similar findings can be seen sporadically in dogs infected with *Sarcocystis canis* and immunohistochemistry would be required to differentiate that protozoal organisms from *Toxoplasma gondii*.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

*Pneumocystis carinii* has also been reported as a sporadic cause of chronic interstitial pneumonia in dogs with a compromised immune system (see Equine Pneumonias).

*Filaroides hirthi*, a lungworm of the alveoli and bronchioles of dogs, has long been known as a cause of mild subclinical infection in large colonies of beagle dogs in the United States. However, it can on occasion cause severe and even fatal disease in individual pets, presumably as a result of immunosuppression. Clinical signs may include coughing and terminal respiratory distress. Grossly, the lesions are multifocal subpleural nodules, often with a green hue because of eosinophils, scattered throughout the lungs. Microscopically, these nodules are eosinophilic granulomas associated with larvae or dead worms, as little reaction develops to the live adults.

*Crenosoma vulpis* is a lungworm seen commonly in foxes and sporadically in dogs with access to the intermediate hosts—slugs and snails. The adult lungworms live in small bronchi and bronchioles, causing eosinophilic and catarrhal bronchitis manifested grossly as gray areas of inflammation and atelectasis in the caudal lobes. In some animals, *Crenosoma vulpis* causes bronchiolar goblet cell metaplasia and mucous obstruction.

*Paragonimus kellicotti* in North America and *Paragonimus westermani* in Asia are generally asymptomatic fluke infections in fish-eating species; cats and dogs acquire it in North America by eating crayfish. Gross lesions include pleural hemorrhages when the metacercariae migrate into the lungs. Later, multifocal eosinophilic pleuritis, and cysts up to 7 mm long containing pairs of adult flukes, are found along with eosinophilic granulomas around clusters of eggs. Like many other parasitic pneumonias, lesions and scars are more frequent in the caudal lobes. Pneumothorax can occur if a cyst that communicates with an airway ruptures to the pleural surface.

546

547

*Angiostrongylus vasorum* and *Dirofilaria immitis* are parasites of the pulmonary arteries and right ventricle and, depending on the stage, can produce different forms of pulmonary lesions. Adult parasites can cause chronic arteritis that leads to pulmonary hypertension, interstitial (eosinophilic) pneumonia, pulmonary interstitial fibrosis, congestive right side cardiac failure, and eventually caudal vena caval syndrome. Other lesions include pleural petechial hemorrhages, and in later stages, diffuse pulmonary hemosiderosis, parasitic granulomas and multifocal pulmonary infarcts. Larvae cause also alveolar injury, thickening of the alveolar walls with eosinophils and lymphocytes (interstitial pneumonia) and multifocal granulomas with giant cells.

### 9.2.3.9.6

#### Pneumonias of Cats

Although upper respiratory tract infections are common and important in cats, pneumonias are uncommon except when there is immunosuppression or aspiration of gastric contents. Viral infections such as feline rhinotracheitis and calicivirus may cause lesions in the lungs, but unless there is secondary invasion by bacteria, they do not usually pose a problem (see Specific Diseases of the Nasal Cavity, Feline Diseases).

### 9.2.3.9.6.1

#### Feline pneumonitis

This mild, subclinical bronchointerstitial pneumonia is caused by *Chlamydophila (psittaci) felis*. The term *feline pneumonitis* is a misnomer because the major lesions from chlamydial infections are a severe conjunctivitis and rhinitis (see Nasal Cavity and Sinuses), but pneumonia is mild and transient. Pulmonary lesions are characterized by neutrophilic bronchiolitis, thickening of the alveolar septa because of edema, infiltration of neutrophils and mononuclear cells, type II pneumonocyte hyperplasia,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

and alveolar histiocytosis. The elucidation of the importance of feline viral rhinotracheitis and feline calicivirus has removed *Chlamydophila felis* from its previously overstated importance.

9.2.3.9.6.2

### Bacterial pneumonias of cats

Bacteria from the nasal flora such as *Pasteurella multocida* and *Pasteurella*-like organisms are occasionally associated with secondary bronchopneumonia in cats (Fig. 9-82). *Pasteurella multocida* also causes otitis media and meningitis, but its role as a respiratory pathogen is mainly associated with pyothorax. Interestingly, there are reports of *Pasteurella multocida* pneumonia in older or immunosuppressed human beings acquired through contact with domestic cats. Mycoplasmas are often isolated from the lungs of cats with pulmonary diseases, but are not definitively established as primary pathogens in feline pneumonias.

Cats are susceptible to three types of mycobacterial infections: classical tuberculosis, feline leprosy, and atypical mycobacteriosis. Classical tuberculosis in cats is rare and generally caused by *Mycobacterium bovis*, but also to a lesser extent by *Mycobacterium tuberculosis* and *Mycobacterium avium*. The usual route of infection for feline tuberculosis is oral, through infected milk or meat, so the lesions are mainly in the alimentary tract from where they may disseminate to other organs. The solid and noncaseated appearance of tuberculous nodules is grossly similar to that of neoplasms, so they must be differentiated from pulmonary neoplasms (e.g., lymphosarcoma). Classic tuberculosis with dermal lesions in cats should be differentiated from feline leprosy (localized skin granulomas) caused by *Mycobacterium lepraemurium* and other nonculturable species of acid-fast bacilli. Atypical mycobacteriosis is caused by contamination of a skin wound with saprophytic mycobacteria such as those of the *Mycobacterium avium-intracellulare* complex. Advances in PCR techniques have notably reduced the time required for etiological diagnosis of mycobacteriosis in veterinary diagnostic laboratories.

547

548

Fig. 9-82 Fibrinopurulent bronchopneumonia, lungs, kitten, 5-month-old kitten with history of conjunctivitis, rhinitis, and bacterial pneumonia. Cranioventral consolidation (C) of the right lung involves approximately 40% of lung parenchyma. The consolidated lung is firm, and on the cut surface some exudate is present in major bronchi. (Courtesy Dr. S. McBurney, Atlantic Veterinary College.)

### 9.2.3.9.6.3

#### Mycotic pneumonias of cats

Cryptococcosis (pulmonary *Cryptococcus neoformans*) is the most frequent systemic mycosis in cats, and lesions are akin to those discussed under Pneumonias of Dogs, Mycotic Pneumonias (see [Chapter 14](#)). It occurs worldwide in all species but is diagnosed most frequently in cats, horses, dogs, and human beings. Some healthy dogs and cats harbor *Cryptococcus neoformans* in the nasal cavity and become asymptomatic carriers. Cats that are immunologically compromised such as by feline leukemia virus infection (FeLV), feline immunodeficiency virus (FIV), malnutrition, or corticosteroid treatment, are most susceptible to clinical infection. Lesions can occur in nearly any tissue, resulting in a wide variety of clinical signs. However, granulomatous rhinitis, sinusitis, otitis, pneumonia, ulcerative dermatitis, and meningoencephalitis are most common.

The pulmonary lesion in cryptococcosis is a multifocal granulomatous pneumonia and, like those occurring in other internal organs, they are small, gelatinous, white foci. The gelatinous appearance is because of the broad mucous capsule around the yeast ([Fig. 9-79, B](#)). Microscopically, lesions contain

## Pathologic Basis of Veterinary Disease, 4th Edition

---

great numbers of fungal organisms (4 to 10  $\mu\text{m}$  in diameter without capsule) and only a few macrophages, lymphocytes, and multinucleated giant cells. This thick polysaccharide capsule does not stain well with H&E, and thus there is a large empty space or halo around the yeast.

9.2.3.9.6.4

### Other pneumonias of cats

9.2.3.9.6.4.1

#### Endogenous lipid (lipoid) pneumonia.

This condition is an obscure, subclinical pulmonary disease of cats and occasionally of dogs, which is unrelated to aspiration of foreign material. Although the pathogenesis is not understood, it is presumed that lipids from pulmonary surfactant and from degenerated cells accumulate within alveolar macrophages. The gross lesions are multifocal, white, firm nodules scattered throughout the lungs. Microscopically, the alveoli are filled with foamy, lipid-laden macrophages accompanied by interstitial infiltration of lymphocytes and plasma cells, fibrosis, and alveolar epithelialization.

Lipid (lipoid) pneumonia occurs frequently in the vicinity of cancerous lung lesions in human beings, cats, and dogs. The reason for this association remains unknown and frequently unrecognized by pathologists. Recent investigations suggest that lipids are the breakdown products of neoplastic cells.

9.2.3.9.6.4.2

#### Exogenous lipid pneumonia.

Another form of lipid pneumonia occurs accidentally in cats given mineral oil by their owners in attempts to remove hairballs.

9.2.3.9.6.4.3

#### Aspiration pneumonias.

This condition is common in cats as a result of vomiting, regurgitation, dysphagia, anesthetic complication, or following accidental administration of food, oral medicaments, or contrast media into the trachea (iatrogenic); pulmonary lesions are similar to those described for dogs (see Aspiration Pneumonia in Dogs).

9.2.3.9.6.5

### Parasitic pneumonias of cats

*Aelurostrongylus abstrusus*, known as “feline lungworm,” is a parasite that occurs in cats wherever the necessary slug and snail intermediate hosts are found. It can cause chronic respiratory disease with coughing and weight loss and, sometimes, severe dyspnea and death, particularly if there are secondary bacterial infections. The gross lesions are multifocal, amber, subpleural nodules up to 1 cm in diameter throughout the lungs. On incision, these granulomatous nodules typically contain eggs, larvae, and turbid, viscous exudate. Microscopically, the parasites and their eggs and larvae are in the bronchioles and alveoli where they cause catarrhal bronchiolitis, hyperplasia of submucosal glands and later, granulomatous alveolitis, alveolar fibrosis, and fibromuscular hyperplasia. During routine examination of feline lungs, it is quite common to find fibromuscular hyperplasia in bronchioles and arterioles in otherwise healthy cats. It was alleged in the past that this fibromuscular hyperplasia was a long-term sequela of subclinical infection with *Aelurostrongylus abstrusus*. However, this view has been challenged and thus the pathogenesis and significance of pulmonary fibromuscular hyperplasia in healthy cats remains uncertain.

## Pathologic Basis of Veterinary Disease, 4th Edition

*Toxoplasma gondii*, *Paragonimus kellicotti*, and *Dirofilaria immitis* can also affect cats (see Parasitic Pneumonias of Dogs).

### 9.2.3.10 FETAL AND PERINATAL PNEUMONIAS

#### 9.2.3.10.1 Fetal Pneumonias

Pneumonia is one of the most frequent lesions found in fetuses submitted for postmortem examination, particularly in foals and food-producing animals. Because of autolysis, lack of inflation, and the lungs being at various stages of development, lesions are often missed or misdiagnosed. In the nonaerated fetal lung, the bronchoalveolar spaces are filled with a viscous, locally produced fluid known as “lung fluid” or “lung liquid.” It has been estimated that each hour an ovine fetus produces about 2.5 ml of “lung fluid” per kilogram of body weight. In the fetus, this fluid normally moves along the tracheobronchial tree, reaching the oropharynx, and is swallowed or discharged into the amniotic fluid. At the time of birth, the lung fluid is rapidly reabsorbed from the lungs by alveolar absorption and lymphatic drainage.

Aspiration of amniotic fluid contaminated with meconium and bacteria from placentitis is the most common route by which microbial pathogens reach the fetal lungs. This form of pneumonia is secondary to fetal hypoxia and acidosis (“fetal distress”), which cause the fetus to relax the anal sphincter, release meconium into the amniotic fluid, and in the terminal stages inspire deeply with open glottis, resulting in the aspiration of contaminated fluid (Fig. 9-83). Gross lesions are only occasionally recognized, but microscopic changes are similar to those of a bronchopneumonia. Microscopically, bronchoalveolar spaces contain variable numbers of neutrophils, macrophages, and pieces of meconium that appear as bright yellow material because of its bile content. In contrast to postnatal bronchopneumonia, lesions in fetuses are not restricted to the cranioventral aspects of the lungs, but involve all pulmonary lobes.

In cattle, *Brucella abortus* and *Arcanobacterium (Actinomyces) pyogenes* are two of the most common bacteria isolated from the lungs of aborted fetuses. These bacteria are usually present in large numbers in the amniotic fluid of cows with bacterial placentitis. Inflammation of the placenta interferes with oxygen exchange between fetal and maternal tissue, inducing fetal hypoxia and predisposing the fetus to “breathe” with an open glottis and aspirate inside the amniotic sac. *Aspergillus* spp. (mycotic abortion) and *Ureaplasma diversum* cause sporadic cases of placentitis, which results in fetal pneumonia and abortion.

In addition to aspiration of bacteria, pathogens can also reach the lungs via fetal blood and cause interstitial pneumonia. Listeriosis (*Listeria monocytogenes*), salmonellosis (*Salmonella* spp.), and chlamydiosis (*Chlamydia psittaci*) are the best known examples of blood-borne diseases that cause fetal pneumonia in farm animals. Gross lesions in the lungs are generally undetected, but microscopic lesions include focal necrotizing interstitial pneumonia, and focal necrosis in the liver, spleen, or brain. Fetal bronchiointerstitial pneumonia occurs also in some viral abortions, such as those caused by infectious bovine rhinotracheitis virus and PI-3 virus in cattle and equine viral rhinopneumonitis in horses. Fetal pneumonias in dogs and cats are infrequently described, perhaps because aborted puppies and kittens are rarely submitted for postmortem examination. With advancements in molecular biology techniques, the etiological diagnosis of abortions and their association with pulmonary fetal lesions is rapidly improving.

**Fig. 9-83 Schematic diagram of meconium aspiration resulting from intrauterine hypoxia.** 1, Increased peristalsis and relaxation of anal sphincter. 2, Meconium contamination of amniotic fluid. 3, Meconium in the oropharynx. 4, Intrauterine gasping with open glottis causing aspiration of meconium and amniotic fluid into fetal lung. (Redrawn with permission from Dr. J. Martínez-Burnes, Facultad de Medicina Veterinaria y Zootecnia, Universidad Autónoma de Tamaulipas, México.)

### 9.2.3.10.2 Neonatal Pneumonias and Septicemias

These entities are rather common in newborn animals lacking passive immunity from hypogammaglobulinemia because of the lack of either ingestion or absorption of maternal colostrum (failure of passive transfer). In addition to septicemias causing interstitial pneumonia, farm animals with hypogammaglobulinemia can develop bronchopneumonia by inhalation of bacterial pathogens. These include *Histophilus somni* and *Pasteurella multocida* in calves, *Streptococcus* spp. in foals, and *Escherichia coli*, *Listeria monocytogenes*, and *Streptococcus suis* in pigs.

### 9.2.3.10.3 Meconium Aspiration Syndrome (MAS)

This is an important but preventable condition in human babies that originates when amniotic fluid contaminated with meconium is aspirated during labor or immediately after birth. The pathogenesis of MAS is basically the same as in fetal bronchopneumonia and abortion (Fig. 9-83). Fetal hypoxia, a common event during dystocia or prolonged parturition, causes the fetus to release meconium into the amniotic fluid. Aspiration can occur directly from aspirating contaminated amniotic fluid before delivery

## Pathologic Basis of Veterinary Disease, 4th Edition

(respiratory movements with an open glottis), or immediately after delivery when the meconium lodged in the nasopharynx is carried into the lung with the first breath of air. This latter form of aspiration is prevented in delivery rooms by routine suction of the nasopharynx in meconium-stained babies. MAS is well known in human babies, but the occurrence and significance in animals remains largely unknown. Although pulmonary lesions are generally mild and transient, aspiration of meconium can be life threatening for newborn babies because it is accompanied by neonatal hypoxia and acidosis, and may be followed by pulmonary hypertension and possibly airway hyperreactivity.

549

In the most severe cases of MAS, focal (patchy) atelectasis can be observed grossly in the lung, indicating failure of the lungs to be fully aerated because of the mechanical obstruction and the chemical effect of meconium on pulmonary surfactant (Fig. 9-32). Microscopically, meconium and keratin exfoliated from skin into the amniotic fluid are present in bronchi, bronchioles, and alveoli, accompanied by mild alveolitis characterized by infiltration of leukocytes followed by alveolar macrophages and occasional giant cells.

550

### 9.2.3.11 NEOPLASMS OF THE LUNGS

#### 9.2.3.11.1 General Considerations

Lung cancer in animals is rare, unlike in human beings where the incidence is alarming and continues to be the number one cause of cancer deaths in Canada, the United States, and Europe. Interestingly, prostatic and breast cancers, so much feared by men and women, are a distant second. To say that cigarette smoking is responsible for this epidemic of lung cancer is superfluous. Although dogs have been proposed as valuable “sentinels” for environmental hazards, such as exposure to passive smoking, asbestos, dyes, and insecticides, it is not known if the prevalence of canine lung tumors has increased in the last few years. Alterations in genes (oncogenes) and chromosomes, and changes in biologically active molecules have been linked to lung cancer in recent years.

As with many other forms of cancer, epidemiologic studies indicate that the incidence of pulmonary neoplasms increase with age, but there are still insufficient data to confirm that particular canine or feline breeds have a higher predisposition to spontaneous lung neoplasms.

A standard nomenclature of pulmonary neoplasms in domestic animals is lacking, and as a consequence, multiplicity of names and synonyms occur in the veterinary literature. Some classifications are based on the primary site, whereas others emphasize more the histomorphologic type. The most common types of benign and malignant pulmonary neoplasms in domestic mammals are listed in Table 9-5.

Clinically the signs of pulmonary neoplasia vary with the degree of invasiveness, the amount of parenchyma involved, and locations of metastases. Signs may be vague, such as cough, lethargy, anorexia, weight loss, and perhaps dyspnea. In addition, paraneoplastic syndromes, such as hypercalcemia, endocrinopathies, and pulmonary hypertrophic osteoarthropathy (see Chapter 16) have been associated with pulmonary neoplasms.

#### 9.2.3.11.2 Primary Neoplasms of the Lungs

Primary neoplasms of the lungs arise from cells normally present in the pulmonary tissue and can be epithelial or mesenchymal, although the latter are rare. Primary benign neoplasms of the lungs, such as pulmonary adenomas, are highly unusual in domestic animals. Most primary neoplasms are malignant and

## Pathologic Basis of Veterinary Disease, 4th Edition

appear as solitary masses of variable size that, with time, can metastasize to other areas of the lungs and to distant organs. Without a diligent necropsy, it is sometimes difficult to differentiate primary lung cancer from pulmonary metastasis resulting from malignant neoplasms elsewhere in the body.

Table 9-5 Classification of Pulmonary Neoplasms

### PRIMARY EPITHELIAL ORIGIN

#### Benign

Papillary adenoma

Bronchiolar-alveolar adenoma

#### Malignant

Adenocarcinoma (acinar or papillar)

Squamous cell carcinoma

Adenosquamous carcinoma

Bronchiolar-alveolar carcinoma

Small cell and large cell carcinomas

Anaplastic (undifferentiated) carcinoma

Carcinoid tumor (neuroendocrine)

Ovine (retroviral) pulmonary carcinoma

### PRIMARY MESENCHYMAL ORIGIN

#### Benign

Hemangioma

#### Malignant

Osteosarcoma, chondrosarcoma

Hemangiosarcoma

Malignant histiocytosis

Lymphomatoid granulomatosis

Granular cell tumor

Mesothelioma

### SECONDARY (METASTATIC) LUNG TUMORS

Any malignant tumor metastatic from another body location (e.g., osteosarcoma in dogs, uterine carcinoma in cows, malignant melanoma in horses)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

It is often difficult to determine the precise topographic origin of a neoplasm within the lungs—for instance, whether it originates in the conducting system (bronchogenic carcinoma), transitional system (bronchiolar carcinoma), exchange system (alveolar carcinoma), or bronchial glands (bronchial gland carcinoma). According to the literature, pulmonary carcinomas in animals arise generally from Clara cells or type II pneumonocytes of the bronchioloalveolar region, in contrast to those in human beings, which are mostly bronchogenic. Tumors located at the hilus generally arise from major bronchi and tend to be a solitary large mass with occasional small metastasis to the periphery. In contrast, tumors arising from the bronchioloalveolar region are often multicentric with numerous peripheral metastases in the lung parenchyma. Because of histologic architecture and irrespective of their site of origin, many malignant epithelial neoplasms are frequently classified by the all encompassing term of pulmonary adenocarcinomas.

550

551

Dogs and cats are the species most frequently affected with primary pulmonary neoplasms, largely carcinomas, generally in older animals. The mean age for primary lung tumors is 11 years for dogs and 12 years for cats. Pulmonary carcinomas in other domestic animals are less common, possibly because fewer are allowed to live a natural life span. These neoplasms can be invasive or expansive, have varying color (white, tan, or gray) and texture (soft or firm), and often have areas of necrosis and hemorrhage, which result in a “craterous” or “umbilicate” appearance. This umbilicate appearance is frequently seen in rapidly growing carcinomas in which the center of the tumoral mass undergoes necrosis as a result of ischemia. Some lung neoplasms mimic pulmonary consolidation or large granulomas. Cats with moderately differentiated neoplasms had significantly longer survival time (median, 698 days) than cats with poorly differentiated neoplasms (median, 75 days). Dogs with primary lung neoplasms, grades I, II, and III, had survival times of 790, 251, and 5 days, respectively.

### 9.2.3.11.2.1

#### Ovine pulmonary carcinoma (pulmonary adenomatosis)

This disease, also known as pulmonary adenomatosis and jaagsiekte (from the South African Afrikaans word for “driving sickness”), is a transmissible, retrovirus-induced neoplasia of ovine lungs. It occurs in sheep around the world, with the notable exception of Australia and New Zealand; its incidence is great in Scotland, South Africa, and Peru and unknown, but probably low, in North America. This pulmonary carcinoma behaves very much like a chronic pneumonia, and the “Jaagsiekte sheep retrovirus” shares many epidemiologic similarities with the ovine lentivirus responsible for Maedi and the retrovirus responsible for enzootic nasal carcinoma in ruminants. Pulmonary adenomatosis has been transmitted to goats experimentally, but is not known to be a spontaneous disease in that species.

**Fig. 9-84 Ovine pulmonary carcinoma (pulmonary adenomatosis, jaagsiekte), lung, 3-year-old sheep. A,** Neoplastic cell infiltration involving the cranial and ventral portions of the lung and mainly sparing the dorsal portions of the caudal lung lobe (*N*). The affected lung is enlarged and firm. *Inset:* Papillary proliferation of cuboidal epithelial cells (presumed type II pneumonocytes). H&E stain. **B,** Transverse section of the cranial lobe. Note the solid appearance of the ventral portion (*bottom*) of the lung and the frothy fluid (edema) that originates in the alveolar walls. (*A, Inset, and B, Courtesy Dr. M. Heras, Facultad de Veterinaria, Universidad de Zaragoza, Spain.*)

This disease affects mainly mature sheep but can occasionally affect young stock. Intensive husbandry probably facilitates horizontal transmission by the copious nasal discharge and explains why the disease occurs in Iceland as devastating epizootics with 5% to 80% mortality. Differential diagnosis between maedi and pulmonary adenomatosis often proves difficult because both diseases often coexist in the same flock or in the same animal. Death is inevitable after several months of the initial onset of respiratory signs, and a specific humoral immune response to the Jaagsiekte sheep retrovirus is undetectable in affected sheep.

During the early stages of ovine pulmonary carcinoma, the lungs are enlarged, heavy, and wet and have several firm, gray, variably sized nodules that tend to be located in the cranioventral lobes (Fig. 9-84, A). In the later stages, the nodules become confluent, and large segments of both lungs are diffusely, but not symmetrically, infiltrated by neoplastic cells. On cross section, edematous fluid and a copious mucoid secretion are present in the airways (Fig. 9-84, B). Microscopically the nodules consist of cuboidal or columnar epithelial cells lining airways and alveoli and forming papillary or acinar (glandlike) structures (Fig. 9-84, C). Because the cells have been identified ultrastructurally as originating from both type II alveolar epithelial cells and Clara cells, the neoplasm is considered a “bronchioloalveolar” carcinoma. Sequelae often include secondary bronchopneumonia, abscesses, and fibrous pleural adhesions. Metastases occur to tracheobronchial and mediastinal lymph nodes and to a lesser extent to other tissues, such as pleura, muscle, liver, and kidneys.

551

552

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Clinically, pulmonary adenomatosis is characterized by a gradual loss of condition, sometimes coughing, and respiratory distress, especially after exercise (such as herding or “driving”). Appetite and temperature are normal, unless there are secondary bacterial infections. An important differentiating feature from maedi (interstitial pneumonia) can be observed if the animals are raised by their hind limbs; copious, thin, mucoid fluid, produced by neoplastic cells in the lungs, pours from the nostrils of some animals with pulmonary adenomatosis.

9.2.3.11.2.2

### Carcinoid (neuroendocrine tumor) of the lungs

This neoplasm, presumably arising from neuroendocrine cells, is sporadically seen in dogs as multiple, large, firm pulmonary masses close to the main stem bronchi. It has also been reported in the nasal cavity of horses. Tumor cells are generally polygonal with finely granular, pale, or slightly eosinophilic cytoplasm. Nuclei are small, and mitotic figures are absent or rare.

9.2.3.11.2.3

### Lymphomatoid granulomatosis

This is a rare but interesting disease of human beings, dogs, and cats characterized by nodules or large solid masses in one or more lung lobes. These frequently metastasize to lymph nodes, kidneys, and liver. Microscopically, tumors are formed by large pleomorphic mononuclear (lymphomatoid) cells with a high mitotic rate and frequent formation of binucleated or multinucleated cells. Tumor cells have a distinct tendency to grow around blood vessels and destroy the vascular walls. Lymphomatoid granulomatosis has some resemblance to lymphomas, and phenotypic marking confirms that neoplastic cells are a mixed population of plasma cells, B and T lymphocytes, and histiocytes.

9.2.3.11.3

### Secondary Neoplasms of the Lungs

These are all malignant by definition because they are the result of metastasis to the lungs from malignant neoplasms elsewhere. Because the pulmonary capillaries are the first filter met by tumor emboli released into the vena cava, secondary neoplasms in the lung are relatively common in comparison to primary ones. Secondary tumors can be of epithelial or mesenchymal origin, also. Common metastatic tumors of epithelial origin are mammary, thyroid (Fig. 9-85), and uterine carcinomas; tumors of mesenchymal origin are osteosarcoma (Fig. 9-86, A), and hemangiosarcoma (Fig. 9-86, B), malignant melanoma in dogs, malignant lymphoma in cows, pigs, dogs, and cats (Fig. 9-87); and the recently reported vaccination-site fibrosarcoma in cats. Usually, secondary pulmonary neoplasms are multiple, scattered throughout all pulmonary lobes (hematogenous dissemination), of variable size, and according to the growth pattern, can be nodular, diffuse, or radiating.

The appearance of metastatic neoplasms differs according to the type of neoplasm. For instance, dark red cystic nodules containing blood are indicative of hemangiosarcoma; dark black solid nodules, melanoma; and hard solid nodules (white, yellow, or tan color) with bone spicules, osteosarcoma. The gross appearances of metastatic carcinomas are generally similar to the primary neoplasm and sometimes have umbilicated centers. Proper diagnoses of pulmonary neoplasms in live animals require history, clinical signs, radiographs, cytologic analysis of BAL fluid, and when necessary a lung biopsy. Identification of a specific lineage of neoplastic cells in biopsy or postmortem specimens is often difficult and requires electron microscopy or immunohistochemical techniques. Electron microscopy allows identification of distinctive cellular components, such as osmophilic lamellar phospholipid nephritic bodies in alveolar type II epithelial cells or melanosomes in melanomas. Immunohistochemical staining of intermediate

552

553

## Pathologic Basis of Veterinary Disease, 4th Edition

---

filaments is also helpful in identifying tumor cells, for instance, a metastatic neurofibrosarcoma can be distinguished from an anaplastic hemangiosarcoma by the presence of S-100 protein and factor VIII-related markers.

**Fig. 9-85 Metastatic thyroid carcinoma, lungs, adult dog.** The lungs contain multiple randomly distributed metastatic nodules, which originated from the enlarged and neoplastic left thyroid gland. *(Courtesy Dr. J.M. King, College of Veterinary Medicine, Cornell University.)*

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 9.2.4 PLEURA AND THORACIC CAVITY

The thoracic wall, diaphragm, and mediastinum are lined by the parietal pleura, which reflects onto the lungs at the hilum and continues as the visceral pleura, covering the entire surface of the lungs except at the hilus where the bronchi and blood vessels enter. The space between these two pleurae (pleural space) is only minimal and under normal conditions, contains only traces of clear fluid with a few exfoliated cells. Samples of this fluid are obtained by thoracocentesis, a simple procedure in which a needle is passed into the pleural cavity. Volumetric, biochemical, and cytologic changes in this lubricant fluid are routinely used in veterinary diagnostics.

#### 9.2.4.1 ANOMALIES

Congenital defects are rare and generally of little clinical significance. Cysts within the mediastinum of dogs can be large enough to compromise pulmonary function or mimic neoplasia in thoracic radiographs. These cysts may arise from the thymus (thymic branchial cysts), perinephric tissue (perinephric pseudocyst), bronchi, or from remnants of the branchial pouches and are generally lined by epithelium and surrounded by a capsule of stromal tissue. Anomalies of the thoracic duct cause some cases of chylothorax.

#### 9.2.4.2 DEGENERATIVE DISTURBANCES

##### 9.2.4.2.1 Pleural Calcification

This disorder is commonly found in dogs with chronic uremia. Lesions appear as linear white streaks in parietal pleura, mainly over the intercostal nephritic muscles of the cranial part of the thoracic cavity. The lesions are not functionally significant but indicate a severe underlying renal problem. Vitamin D toxicity (hypervitaminosis D) and ingestion of hypercalcemic substances, such as vitamin D analogs, can also cause calcification of the pleura and other organs.

553

554

##### 9.2.4.2.2 Pneumothorax

This disorder is the presence of air in the thoracic cavity where there should normally be negative pressure to facilitate inspiration. Human beings have a complete and strong mediastinum so that pneumothorax is generally unilateral and thus not a serious problem. In dogs the barrier is variable, but in general less complete, so often some communication exists between left and right sides.

There are two main forms of pneumothorax. In spontaneous pneumothorax, air leaking into the pleural cavity occurs without any known underlying disease or trauma. In secondary pneumothorax, movement of air into the pleural cavity results from an underlying pulmonary or thoracic wall disease. Most common causes of secondary pneumothorax in veterinary medicine are penetrating wounds to the thoracic wall, ruptured esophagus, iatrogenic trauma to thorax and lung during a transthoracic lung biopsy or thoracoscopy, tracheal rupture from improper intubation, and rupture of emphysematous bullae or parasitic pulmonary cysts (*Paragonimus* spp.) that communicate with the thoracic cavity. Pneumothorax and pneumomediastinum due to high air pressure (barotrauma) are also well documented in cats after equipment failure during anesthesia. Clinical signs of pneumothorax include respiratory distress, and the lesion is simply a collapsed, atelectatic lung. The air is readily reabsorbed from the cavity if the site of entry is sealed.

### 9.2.4.3 CIRCULATORY AND LYMPHATIC DISTURBANCES

#### 9.2.4.3.1 Pleural Effusion

This general term is used to describe accumulation of any fluid (transudate, modified transudate, exudate, blood, lymph, or chyle) in the thoracic cavity. Cytologic and biochemical evaluations of pleural effusions are sometimes helpful in suggesting a possible pathogenesis. Based on protein concentration and total numbers of nucleated cells, pleural effusions are cytologically divided into transudates, modified transudates, and exudates.

#### 9.2.4.3.2 Hydrothorax

When the fluid is serous, clear, and odorless, and fails to coagulate when exposed to air, the condition is referred to as hydrothorax (transudate). Causes of hydrothorax are the same as those involved in edema formation in other organs: increased hydrostatic pressure (heart failure), decreased oncotic pressure (hypoproteinemia, as in liver disease), alterations in vascular permeability (ANTU toxicity), or obstruction of lymph drainage (neoplasia). In cases where the leakage is corrected, if the fluid is a transudate, it is rapidly reabsorbed. If the fluid persists, it irritates the pleura and causes mesothelial hyperplasia and fibrosis, which thickens the pleura.

In severe cases, the amount of fluid present in the thoracic cavity can be considerable. For instance, a medium size dog can have 2 L of fluid, and a cow may accumulate 25 L or more. Excessive fluid in the thorax causes compressive atelectasis, resulting in respiratory distress ([Fig. 9-34](#)). Hydrothorax is most commonly seen in cattle with right side heart failure or cor pulmonale; dogs with congestive heart failure, chronic hepatic disease (hepatic hydrothorax) ([Fig. 9-88](#)) or nephrotic syndrome; pigs with mulberry heart disease; and horses with African horse sickness.

#### 9.2.4.3.3 Hemothorax

Blood in the thoracic cavity is called hemothorax, but the term has been used for exudate with a sanguineous component. Causes include rupture of a major blood vessel as a result of severe thoracic trauma (e.g., hit by car), erosion of a vascular wall by malignant cells or inflammation (e.g., aortitis caused by *Spirocerca lupi*), or ruptured aortic aneurysms, clotting defects (coagulopathies as in warfarin toxicity), disseminated intravascular coagulation (consumption coagulopathy), and thrombocytopenia due to bone marrow suppression. Hemothorax is generally acute and fatal. On gross examination, the thoracic cavity can be filled with blood, and the lungs are partially or completely atelectatic ([Fig. 9-89](#)).

Fig. 9-88 **Hydrothorax (hepatic hydrothorax) and hepatic cirrhosis, pleural cavity, 8-year-old dog.** The pleural cavity contains a large amount of dark yellow transudate (\*) (ventrally). The lungs show focal lobular atelectasis. Fluid in the thoracic cavity can compress the ventral portions of the lung. Also note the nodular surface of the cirrhotic liver (L). (Courtesy Dr. S. McBurney, Atlantic Veterinary College.)

554

Fig. 9-89 **Hemothorax, right pleural cavity, dog.** The right pleural cavity is filled with a large clot of blood from a ruptured thoracic aortic aneurysm, which caused unexpected death. Canine aortic aneurysms are associated with migration of *Spirocerca lupi* larvae along the aortic wall before their final migration into the wall of the adjacent esophagus. (Courtesy Dr. A. López, Atlantic Veterinary College.)

555

## Pathologic Basis of Veterinary Disease, 4th Edition

---

9.2.4.3.4

### Chylothorax

The accumulation of chyle (lymph rich in triglycerides) in the thoracic cavity ([Fig. 9-90](#)) is a result of the rupture of major lymph vessels, usually the thoracic duct or the right lymphatic duct. The clinical and pathologic effects of chylothorax are similar to those of the other pleural effusions. Causes include thoracic neoplasia (the most common cause in human beings, but a distant second to idiopathic cases in dogs), trauma, congenital lymph vessel anomalies, fungal infections, dirofilariasis, and iatrogenic rupture of the thoracic duct during surgery. The source of the leakage of chyle is rarely found at necropsy. When the leakage of chyle occurs in the abdominal cavity, the condition is referred to as chyloabdomen.

9.2.4.4

### INFLAMMATION OF THE PLEURA

Pleural tissue is readily susceptible to injury caused by direct implantation of an organism through a penetrating thoracic or abdominal wound, by hematogenous dissemination of infectious organisms in septicemias, or by direct extension from an adjacent inflammatory process, such as in fibrinous bronchopneumonia or from a perforated esophagus. Chronic injury typically results in serosal fibrosis and tight adhesions between visceral and parietal pleurae. In severe cases, these adhesions can obliterate the pleural space.

9.2.4.4.1

### Pleuritis or Pleurisy

Inflammation of the visceral or parietal pleurae is called pleuritis and, according to the type of exudate, can be fibrinous, suppurative, granulomatous, hemorrhagic, or a combination of exudates. When suppurative pleuritis results in accumulation of purulent exudate in the cavity, the lesion is called pyothorax or thoracic empyema ([Fig. 9-91](#)). Clinically, pleuritis causes considerable pain, and in addition, empyema can result in severe toxemia. Pleural adhesions and fibrosis are the most common sequelae of chronic pleuritis and can notably interfere with inflation of the lungs.

Fig. 9-90 **Chylothorax (cause unknown), thoracic (pleural) cavity, mink.** Lymph (chyle) fills both the left and right pleural cavities. The heart (*H*) and pericardium are essentially normal because the chyle does not adhere to the outer surface of the pericardial sac, as typically happens with suppurative and fibrinous exudates in the thoracic cavity. (Courtesy Western College of Veterinary Medicine.)

Pleuritis can occur as an extension of pneumonia, particularly in fibrinous bronchopneumonias (pleuropneumonia), or it can occur alone, without obvious pulmonary involvement (Fig. 9-92). Bovine and ovine pneumonic manheimiosis and porcine and bovine pleuropneumonia are good examples of pleuritis associated with fibrinous bronchopneumonias. Polyserositis in pigs and pleural empyema, particularly in cats and horses, are examples of pleural inflammation in which involvement of the lungs may not accompany the pleurisy. Pleuritis is most frequently caused by bacteria, which cause polyserositis reaching the pleura hematogenously. These bacteria include *Haemophilus parasuis* (Glasser's disease), *Streptococcus suis* type II, and some strains of *Pasteurella multocida* in pigs; *Streptococcus equi* ssp. *equi*. and *Streptococcus zooepidemicus* ssp. *zooepidemicus* in horses; *Escherichia coli* in calves; and *Mycoplasma* spp. and *Haemophilus* spp. in sheep and goats. Contamination of pleural surfaces can be the

555

556

## Pathologic Basis of Veterinary Disease, 4th Edition

result of extension of a septic process (e.g., puncture wounds of the thoracic wall and in cattle traumatic reticulopericarditis) and ruptured pulmonary abscesses (e.g., *Arcanobacterium* [*Actinomyces*] *pyogenes*).

**Fig. 9-91 Pyothorax (*Pasteurella multocida*), right pleural cavity, cat.**  
Large amounts of purulent exudate cover the visceral and parietal pleurae. This lesion is also referred to as pleural empyema.  
(Courtesy Dr. A. López, Atlantic Veterinary College.)

In dogs and cats, bacteria (such as *Nocardia*, *Actinomyces*, and *Bacteroides*) can cause pyogranulomatous pleuritis, characterized by accumulation of blood-stained pus (“tomato soup”) in the thoracic cavity. This exudate usually contains yellowish flecks called “sulfur granules” (Fig. 9-93), although these are less common in nocardial empyema in cats. Many species of bacteria, such as *Escherichia coli*, *Arcanobacterium pyogenes*, *Pasteurella multocida*, and *Fusobacterium necrophorum*, can be present in pyothorax of dogs and cats. These bacteria occur alone or in mixed infections. The pathogenesis of pleural empyema in cats is still debatable, but bite wounds or penetration of foreign material (migrating grass awns) are likely. Pyogranulomatous pleuritis with empyema occurs occasionally in dogs, presumably associated with inhaled small plant material, penetrating (migrating) grass awns, and nasal flora microorganisms. Because of their physical shape (barbed) and assisted by the respiratory movement, aspirated grass awns can penetrate airways, move through the pulmonary parenchyma, and eventually perforate the visceral pleura causing pyogranulomatous pleuritis.

Fig. 9-92 **Fibrinous pleuritis, right pleural cavity, horse.** **A**, Large masses of yellow fibrin cover the visceral and parietal pleurae. The lungs are normal. **B**, The visceral pleura is covered by a thick layer of fibrin. Subjacent alveoli are essentially normal. H&E stain. (**A**, Courtesy Dr. A. López, Atlantic Veterinary College. **B**, Courtesy College of Veterinary Medicine, University of Illinois.)

Cats with the noneffusive (“dry”) form of feline infectious peritonitis frequently have focal pyogranulomatous pleuritis, in contrast to those with the “wet” or “effusive” form, in which thoracic involvement is primarily that of a pleural effusion. Cytologic evaluation of the effusion typically shows a

## Pathologic Basis of Veterinary Disease, 4th Edition

high cellularity with many degenerated leukocytes, lymphocytes, macrophages, and mesothelial cells, and a pink granular background as a result of the high protein content.

Pleuritis is also an important problem in horses. *Nocardia asteroides* and *Nocardia brasiliensis* can cause fibrinopurulent pneumonia and pyothorax with characteristic sulfur granules. Although *Mycoplasma felis* can be isolated from the respiratory tract of normal horses, it is also isolated from horses with pleuritis and pleural effusion, particularly during the early stages of infection.

**Fig. 9-93 Nocardiosis.** **A**, Chronic pleuritis (*Nocardia asteroides*), pleural cavity, cat. The pleural cavity holds abundant red-brown exudate (“tomato soup”). Once considered to be pathognomonic of *Nocardia* infection, it is no longer regarded as being diagnostic of nocardiosis. The fluid contains granulomatous inflammatory cells and sulfur granules. **B**, Chronic pleuritis (*Nocardia asteroides*), visceral pleura, dog. The thickened pleura has a granular appearance because of granulomatous inflammation and the proliferation of fibrovascular tissue of the pleura. **C**, Chronic pleuritis (*Nocardia asteroides*), thoracic cage, dog. The pleura has been thrown up into villouslike projections composed of abundant fibrovascular tissue and granulomatous inflammation. Leakage from the neocapillaries of the fibrovascular tissue is responsible for the hemorrhagic appearance of the pleural exudate. H&E stain. **D**, Chronic pleuritis (*Nocardia asteroides*), parietal pleura, cat. Large pieces of exudate, which contain sulfur granules, are present on the thickened pleura. (**A**, **B**, and **C**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **D**, Courtesy College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

9.2.4.5

### NEOPLASMS

557

The pleural surface of the lung is often involved in neoplasms that have metastasized from other organs to the pulmonary parenchyma and rupture of the visceral pleura to seed the pleural cavity. Mesothelioma is the only primary neoplasm of the pleura.

9.2.4.5.1

### Mesothelioma

This rare neoplasm of the thoracic, pericardial, and peritoneal mesothelium of human beings and most domestic animals is seen most commonly in calves, in which it can be congenital. In human beings, it has long been associated with inhalation of certain types of asbestos fibers (asbestos mining, ship building) alone or with cigarette smoking as a probable cocarcinogen; no association between the incidence of mesothelioma and exposure to asbestos has been made convincingly in domestic animals. In animals, there may be pleural effusion with resulting respiratory distress, cough, and weight loss.

Mesothelioma frequently starts causing a thoracic effusion, but cytological diagnosis can be difficult because of the morphologic resemblance of malignant and reactive mesothelial cells. During inflammation, mesothelial cells become reactive and not only increase in number, but also become pleomorphic and form multinucleated cells that may be cytologically mistaken for a carcinoma.

557

558

**Fig. 9-94 Mesothelioma (M), lungs and heart, horse.** The tumor has proliferated and extended over the ventral parietal pleura and pericardium. The pericardial sac has been opened, and the epicardium appears essentially normal, indicating that the tumor did not invade the pericardial sac. (Courtesy Dr. J.M. King College of Veterinary Medicine, Cornell University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Grossly, mesothelioma appears as multiple, discrete nodules or arborescent, spreading growths on the pleural surface (Fig. 9-94). Microscopically, either the mesothelial covering cells or the supporting tissue can be the predominant malignant component, so the neoplasm can appear microscopically as a carcinoma or as a fibrosarcoma. Although considered malignant, mesotheliomas rarely metastasize.

Secondary tumors may also spread into the visceral and parietal pleura. Thymomas are rare neoplasms that grow in the cranial mediastinum of adult or aged dogs, cats, pigs, cattle, and sheep. Thymomas are composed of thymic epithelium and lymphocytes (see Chapter 13).

### 9.3 ACKNOWLEDGMENT

I thank Dr. William Yates (Canadian Food Inspection Agency) for having provided the basis of this chapter; all pathologists at the Atlantic Veterinary College for providing case material; Dr. Julio Martínez-Burnes, University of Tamaulipas, Mexico, for his suggestions; and Dr. Shannon Martinson, Atlantic Veterinary College, for reviewing the text. Finally, I acknowledge Dr. Reginald G. Thomson (deceased), former Dean of the Atlantic Veterinary College, for years of advice, and Rosalie and Adriana for their support.

## 10 Chapter 10 Cardiovascular System

JOHN F. VAN VLEET

VICTOR J. FERRANS

### 10.1 HEART

#### 10.1.1 INTRODUCTION

##### 10.1.1.1 NORMAL MORPHOLOGY

The heart is a conical, muscular organ that in mammals and birds has evolved into a four-chambered pump with four valves. During early fetal development, the heart is converted from an elongated muscular tube into a C-shaped structure by a process termed looping. Subsequently, septation occurs to produce the right and left atrial and ventricular chambers and separation of the common truncus arteriosus into the aorta and pulmonary artery. The heart lies within a fibroelastic sac, the pericardium, which normally contains a small amount of clear, serous fluid. The heart is interposed as a pump into the vascular system, with the right side supplying the pulmonary circulation and the left side the systemic circulation.

The wall of the heart is composed of three layers: the epicardium, the myocardium, and the endocardium. The epicardium, the outermost layer of the heart, is the visceral pericardium, which is continuous at the cardiac base, with the parietal pericardium. The entire inner surface of the pericardial cavity is covered by mesothelium. The subepicardial layer is attached to the myocardium and consists of a thin layer of fibrous connective tissue, variable but generally abundant amounts (in well-nourished animals) of adipose tissue, and numerous blood vessels, lymph vessels, and nerves ([Fig. 10-1](#)).

The myocardium is the muscular layer of the heart. It consists of cardiac muscle cells (myocytes) arranged in overlapping spiral patterns. These sheets of cells are anchored to the fibrous skeleton of the heart, which surrounds the atrioventricular valves and the origins of the aorta and pulmonary artery. The myocardial thickness is related to the pressure present in each chamber; thus the atria are thin walled and the ventricles are thicker. The thickness of the left ventricular free wall is approximately threefold that of the right ventricle, measured in a transverse section across the middle of the ventricles, because the pressure is greater in the systemic circulation than in the pulmonary circuit.

The endocardium is the innermost layer of the heart and lines the chambers and extends over projecting structures, such as the valves, chordae tendineae, and papillary muscles. The endocardium of the atria is thicker than that of the ventricles and thus normally appears more pale at gross examination. The surface of the endocardium is endothelium that lies on a thin layer of connective tissue; the subendocardial layer contains blood vessels, nerves, and connective tissue. Purkinje fibers are distributed in the subendocardium throughout both ventricles.

The arterial supply to the heart is the left and right coronary arteries, which arise from the aorta at the sinuses of Valsalva behind the left and right cusps of the aortic valves. The arteries course over the heart in the subepicardium and give off perforating intramyocardial arteries that supply a rich capillary bed throughout the myocardium. Extensive anastomoses occur between the capillaries that tend to run parallel to the

## Pathologic Basis of Veterinary Disease, 4th Edition

elongated cardiac muscle cells. The ratio of the area of capillaries to that of muscle cells is approximately 1:1, a fact evident when the myocardium is viewed in cross section.

The cardiac conduction system is infrequently examined in animals because it is a labor-intensive process. Exceptions are cases with documented electrocardiographic alterations of undetermined origin. Components include (1) the sinoatrial (SA) node at the junction of the cranial vena cava and the right atrium; (2) the atrioventricular (AV) node located beneath the septal leaflet of the tricuspid valve, and the AV bundle traversing the lower atrial septum onto the dorsal portion of the muscular interventricular septum; and (3) the right and left bundle branches that descend on each side of the muscular interventricular septum and eventually ramify in the ventricular myocardium as the Purkinje fiber network.

559

560

**Fig. 10-1 Normal heart, pig.** A, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle. (Courtesy School of Veterinary Medicine, Purdue University.)

The cardiac valves (tricuspid valve [right atrioventricular valve], mitral valve [left atrioventricular valve], aortic valve, and pulmonary valve) are attached to fibrous rings and have thin avascular cusps. The valves open and close to regulate blood flow through the heart. During embryogenesis, endocardial cushions (mesenchymal tissue covered by endothelium) are precursors of the valve cusps. By remodeling, growth, and elongation, the cushions become thin mature cusps composed of connective tissue with an endothelial covering.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Occasionally, normal features in animal hearts can be misinterpreted as lesions. The epicardial lymph vessels, especially in cattle, can appear as prominent white streaks that could be interpreted as areas of necrosis. The septal cusp of the tricuspid valve in dogs is normally rather tightly attached to the ventricular septum. In young ruminants up to 2 to 3 weeks of age, the ductus arteriosus and foramen ovale can be probe patent, but unless the openings are large, no significant shunting of blood is likely to occur during life. The overall shape of normal hearts can vary from the elongated conical profile in the horse to the somewhat rounded shape in the dog. Cardiac weights vary greatly among species and breeds; pigs have relatively small hearts (approximately 0.3% of body weight) and dogs have relatively large hearts (from 0.75% of body weight in nonathletic breeds to 1.25% in athletic breeds).

Postmortem alterations in hearts must be recognized and correctly interpreted. Rigor mortis occurs in myocardium much as in skeletal muscles and produces contracted, rigid ventricular walls, which empties the more muscular left ventricle. After rigor passes, the ventricular walls relax.

Postmortem blood clotting produces red (“currant jelly”) clots in the atria, right ventricle, and large vessels at the base of the heart. Postmortem blood clots are found in these anatomic structures because they lack contractile elements (large vessels) or have less muscle mass (atria, right ventricle) to undergo contraction during rigor mortis. In postmortem evaluations of the heart, it is important to note the presence (or absence) of blood clots in the ventricles and their appearance (“currant jelly” versus “chicken fat”) (Fig. 10-2). Under normal conditions, because of its larger chamber volume and thinner walls, a blood clot will be found in the right ventricle, whereas little or no blood clot will be found in the left ventricle because of its smaller chamber volume and thicker walls. Animals with prolonged heart disease may lack adequate glycogen reserves in cardiac myocytes. As a result, the ventricular chambers may fail to contract during rigor mortis, allowing a blood clot to form in the left ventricle.

560

561

**Fig. 10-2 Postmortem “chicken fat” clot, dog.** Note how the clot conforms to the shape of the lumens of the vessels from which it was removed. Chicken fat clots consist primarily of clotted plasma and fibrin and other proteins of the coagulation cascade. They are often indicative of anemia; however, in all animals their formation by the separation of the red blood cells from the rest of the components of blood depends on the erythrocyte sedimentation rate (ESR). Separation can occur in all animals in response to systemic inflammation, which increases the ESR, but the horse normally has a high ESR because equine erythrocytes clump together in rouleau formation, which increases the ESR. Thus depending on the ESR, postmortem clots may be pale white to yellow (“chicken fat” clot) or shiny red (“currant jelly” clot) or sometimes a mixture. *(Courtesy Dr. R.K. Myers, College of Veterinary Medicine, Iowa State University.)*

Occasionally, pale “chicken fat” clots that contain reduced numbers of erythrocytes form in animals with severe anemia, systemic inflammatory disease, leukemia, or after prolonged agonal periods. Horses more often have pale clots because of a rapid erythrocyte sedimentation rate termed rouleaux formation. Postmortem lysis of erythrocytes followed by imbibition of hemoglobin produces diffuse red staining of the endocardium and epicardium and simulates the appearance of hemorrhage.

Other potentially misleading findings at necropsy of young dogs and horses include diffuse or patchy myocardial pallor that subsequently fails to correlate with any detectable microscopic alterations. Also, the intracardiac injection of euthanasia solution and other substances can cause hemopericardium and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

myocardial pallor from tissue dissolution and from crystalline deposits at the site of solution deposition (Fig. 10-3).

Cardiac muscle cells are surrounded by interstitial components, which include blood and lymph vessels, nerves, and connective tissue cells such as fibroblasts, histiocytes, mast cells, pericytes, primitive mesenchymal stem cells and extracellular matrix elements of connective tissue, including collagen fibrils, elastic fibers, and acid mucopolysaccharides. Cardiac muscle cells can be divided into two populations: the working myocytes and the specialized fibers of the conduction system. The working myocyte is a cross-striated branching fiber of an irregular cylindrical shape that measures 60 to 100  $\mu\text{m}$  in length and 10 to 20  $\mu\text{m}$  in diameter, with centrally located, elongated nuclei. Myocytes in young animals are smaller and have small amounts of sarcoplasm. Atrial myocytes are smaller than ventricular myocytes. Adjacent myocytes are joined end-to-end by specialized junctions known as intercalated disks and less frequently by side-to-side connections termed lateral junctions. Multinucleated fibers with nuclei arranged in central rows are

561

frequently seen in hearts of growing pigs (Fig. 10-4, A). The myocytes of old animals commonly have large polyploid nuclei. The cytoplasm (sarcoplasm) of myocytes is largely occupied by the contractile proteins that are highly organized into sarcomeres, the repeating contractile units of the myofibril. Myofibrils are formed by end-to-end attachment of many sarcomeres. The cross-striated or banded appearance of myocytes is the result of sarcomeric organization into A bands composed of myosin in the form of “thick” filaments (12 to 16 nm in diameter), I bands composed of actin in the form of “thin” filaments (5 to 8 nm in diameter), and dense Z bands at the end of each sarcomere. Thick and thin filaments interdigitate and provide the basis for the sliding mechanism of muscle contraction. Myocytes are enclosed by the sarcolemma, which consists of the plasma membrane and the covering basal lamina (external lamina). Other important components of cardiac muscle cells are generally only apparent in electron micrographs and include abundant mitochondria, a highly organized network of intracellular tubules termed the sarcoplasmic reticulum, cylindrical invaginations of the plasma membrane called T tubules, ribosomes, cytoskeletal filaments, glycogen particles, lipid droplets, Golgi complexes, atrial granules (contain atrial natriuretic factor), lysosomes, and residual bodies (Fig. 10-4, B).

562

**Fig. 10-3 Myocardial necrosis, intracardiac injection, euthanasia solution, left ventricle, dog.** Injections of barbiturates and other euthanasia solutions into the myocardium itself will cause localized hemorrhage and myocardial destruction at the injection site (*arrow*). Injections into the ventricle will cause endocardial hemorrhage and necrosis (not shown). (*Courtesy College of Veterinary Medicine, University of Illinois.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

The morphologic features of the cardiac muscle cells of the specialized conduction tissues, including the sinoatrial node, atrioventricular node, atrioventricular bundle (bundle of His), and bundle branches, vary greatly at different sites and among animal species but generally are thin fibers surrounded by abundant fibrous connective tissue and have only small amounts of contractile material. The Purkinje fibers are distinguished by their large diameters (in horse, ox) and abundant pale eosinophilic sarcoplasm rich in glycogen and poor in myofibrils.

**Fig. 10-5 Schematic diagram of cardiac muscle cells.** Growth disturbances of atrophy and hypertrophy. (Redrawn with permission from School of Veterinary Medicine, Purdue University.)

10.1.1.2

### REACTION TO INJURY

Cardiac muscle cells respond to injury by a limited spectrum of reactions. Reversible morphologic alterations include cellular growth disturbances that lead to atrophy or hypertrophy (Fig. 10-5). Various sublethal injuries or degenerations, such as fatty degeneration, lipofuscinosis, vacuolar degeneration, and myocytolysis, result in distinctive myocyte alterations (Fig. 10-6). Lethal injury to myocytes results in necrosis or apoptosis (Fig. 10-7).

Necrosis of cardiac muscle cells is generally followed by leukocytic invasion and phagocytosis of sarcoplasmic debris. The end result is persistence of collapsed sarcolemmal “tubes” of basal lamina surrounded by condensed interstitial stroma and vessels. Lesions with severe disruption of the myocardium have residual changes of fibroblastic proliferation and collagen deposition to form scar tissue. Regeneration of cardiac muscle cells generally does not occur, except in less evolved animals, such as amphibians and

## Pathologic Basis of Veterinary Disease, 4th Edition

fish, and in certain inbred mouse strains. The continual contraction of intact cardiac muscle cells impairs the mechanisms for regeneration. Also, in hearts of neonatal animals and more often in avian hearts, a limited amount of myocyte regeneration has been reported. Recent studies indicate that stem cells exist in adult animal and human hearts and, with myocardial injury, these cells may differentiate into cardiac muscle cells. However, the extent of myocyte regeneration is probably minimal. Hyperplasia of myocytes is a normal component of cardiac growth in the first several months of life. Then proliferation ceases. Normal growth then is the result of hypertrophy of myocytes until cell sizes normal for the species are reached.

562

563

## Pathologic Basis of Veterinary Disease, 4th Edition

Apoptosis (programmed cell death of myocytes) is increasingly recognized for its role in the development of various myocardial lesions and cardiac diseases. These conditions include cardiac development, ischemic injury, several types of experimentally induced heart failure (ischemia-reperfusion, hypoxia, pressure-overload hypertrophy), and cardiotoxicity. In some cell systems, apoptosis can be triggered by the presence of excessive amounts of oxygen free radicals. Cells dying by apoptosis shrink and form apoptotic bodies. In contrast to cell death by necrosis, apoptosis is not accompanied by an inflammatory reaction and fibrosis.

Histopathologic study of sections of the myocardium is substantially limited in respect to specific diagnoses and only rarely can an etiologic diagnosis be made from the morphologic alterations. This inadequacy exists because the spectrum of pathologic reactions is a limited one, and many agents that damage the heart produce similar lesions. Myocardial necrosis can be confused with myocardial inflammation with secondary necrosis because both lesions have substantial leukocytic infiltration. Some animals that die peracutely from cardiac failure lack detectable microscopic alterations and are presumed to have suffered from an arrhythmic episode resulting in syncope. Hearts with long-standing myocardial damage have foci of fibrosis, regardless of the cause of the loss of myocytes. Correlation between the severity of clinical cardiac disease and the severity of myocardial injury can be poor: a small lesion at a critical site, such as a portion of the conduction system can be fatal, whereas a widespread myocardial lesion, such as myocarditis, can be asymptomatic.

563

564

**Fig. 10-7 Schematic diagram of the sequential events in myocardial necrosis.** A, Various injuries lead to (B) hyaline necrosis or apoptosis of myocyte. ### 10.1.1.3 CARDIAC PATHOPHYSIOLOGY

The results of normal cardiac function include the maintenance of adequate blood flow, called cardiac output, to peripheral tissues that provide delivery of oxygen and nutrients, the removal of carbon dioxide and other metabolic waste products, the distribution of hormones and other cellular regulators, and the maintenance of adequate thermoregulation and glomerular filtration pressure (urine output). The normal heart has a threefold to fivefold functional reserve capacity, but this capacity can eventually be lost in cardiac disease and the result is impaired function. Compensatory mechanisms operate in both normal and diseased hearts in an attempt to meet both the short-term and long-term demands for adequate cardiac output. These mechanisms include cardiac dilation, myocardial hypertrophy, increase in heart rate, increase in peripheral resistance, increase in blood volume, and redistribution of blood flow. These compensatory mechanisms can maintain cardiac output that is adequate for some time, even in animals with rather severe cardiac disease sufficient to compromise cardiac function from loss of myocardial contractility, sustained pressure overload, or sustained volume overload.

Cardiac dilation can occur as a terminal lesion in many cardiac diseases (Fig. 10-8, A). As a compensatory response to achieve increased cardiac output, dilation allows stretching of cardiac muscle cells to increase contractile force according to the Frank-Starling phenomenon, and increased stroke volume is the result. However, stretching beyond certain limits decreases contractile strength.

564  
565

Fig. 10-8 **Cardiac dilation and hypertrophy, heart, transected ventricles, dog.** **A**, Cardiac dilation. Note the thin walls of both dilated ventricles. LV, Left ventricle. **B**, Cardiac hypertrophy (fixed tissue). Note that the right ventricular and left ventricular (LV) walls are approximately the same thickness, indicating that there is right ventricular hypertrophy. (**A**, Courtesy Dr. Y. Niyo, College of Veterinary Medicine, Iowa State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy College of Veterinary Medicine, University of Florida; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Myocardial hypertrophy is an important long-term compensatory response of the heart to maintain adequate cardiac output in the face of increased pressure or volume overload (see Myocardial Diseases) (Fig. 10-8, B).

### 10.1.1.4 CIRCULATORY DISTURBANCES

Hemorrhage is a frequent lesion of the epicardium, endocardium, and myocardium. Hemorrhages vary in size from petechiae (1- to 2-mm diameter), to ecchymoses (2- to 10-mm diameter), to suffusive (diffuse). Animals dying from septicemia, endotoxemia, anoxia, or electrocution often have prominent epicardial (Figs. 10-9 and 10-10) and endocardial (Fig. 10-11) hemorrhages. Horses dying of any cause usually have agonal hemorrhages on the epicardial and endocardial surfaces. A distinctive example of a specific disease with cardiac hemorrhage is mulberry heart disease, associated with selenium—vitamin E deficiency in growing pigs. In these pigs, hydropericardium accompanies severe myocardial hemorrhage that results in a red, mottled (mulberry-like) appearance of the heart.

565

566

**Fig. 10-9 Epicardial hemorrhage, petechiae and ecchymoses, endotoxemia, heart, cow.** Note the epicardial and subepicardial hemorrhages in the fat of the coronary groove (a common site). Petechiae and ecchymoses are often attributable to severe septicemia, endotoxemia, anoxia, or electrocution. In this case, the hemorrhage resulted from injury to the endothelium from endotoxin (component of the cell wall of gram-negative bacteria). The smaller, pinpoint hemorrhages (1 to 2 mm) are petechiae. The larger hemorrhages (3 to 5 mm) are ecchymoses. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 10-11 Endocardial suffusive hemorrhage, heart, left ventricle, calf.** A red to dark-red sheet of suffusive hemorrhage is present in the endocardium of the left ventricle. Suffusive hemorrhage is often attributed to severe septicemia, endotoxemia, anoxia, or electrocution. (Courtesy College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 10.1.1.5 SYNDROMES OF CARDIAC FAILURE OR DECOMPENSATION (TABLE 10-1)

Cardiac syncope, an acute expression of cardiac disease, is characterized clinically by collapse, loss of consciousness, and extreme changes in heart rate and blood pressure, and with or without demonstrable lesions. Syncope can be caused by massive myocardial necrosis, ventricular fibrillation, heart block, arrhythmias, and reflex cardiac inhibition (e.g., that associated with high intestinal blockage).

Congestive heart failure usually develops slowly from gradual loss of cardiac pumping efficiency associated with either pressure or volume overload or myocardial damage (Figs. 10-12 and 10-13; also see Figs. 8-34 and 8-35). Pathogenetically, congestive heart failure is initiated by development of cardiac disease (myocardial, valvular, congenital, etc.) or increased workload associated with pulmonary, renal, or vascular disease leading to loss of cardiac reserve and development of decreased blood flow to peripheral tissue (forward failure) and accumulation of blood behind the failing chamber (backward failure). Reduced renal blood flow creates hypoxia in the kidneys and increases renin release from the juxtaglomerular apparatus, resulting in stimulation of aldosterone release from the zona glomerulosa of the adrenal cortex. Sodium and water retention are the results of the action of aldosterone on the renal tubules; increased plasma volume follows, as does accumulation of edema fluid (mainly in body cavities). Hypoxia also stimulates increased erythropoiesis in bone marrow and extramedullary organs, such as the spleen, causing polycythemia and thus increased viscosity of the blood. The hypervolemia from aldosterone-induced water retention increases the workload on the already failing heart. Thus a vicious cycle of cardiac decompensation is initiated that will lead to death from cardiac failure unless therapeutic intervention occurs. Cardiac dilation, hypertrophy, and increased heart rate can provide some compensation for the increased workload.

566

567

**Fig. 10-12 Subcutaneous edema, high altitude disease with congestive heart failure (“brisket disease”), presternal, sternal, and caudal sternocephalic regions (brisket), cow.** The extensive subcutaneous edema is the result of chronic congestive heart failure. Table 10-1 Experimental Models of Heart Failure

Experimental Model	Experimental Method	Species
Pressure loading	Pulmonary artery banding	Rat, dog, pig, sheep, pony
	Aortic constriction	Rat, rabbit, dog, sheep
	Supravalvular aortic constriction	Dog
	Aortic valve stenosis	Rabbit, dog
	Pulmonary valve stenosis	Dog
Volume loading	Experimental hypertension	Rat, dog
	Fluid overload	Baboon
	Aorta-to-vena cava fistula	Rat, dog
	Aortic valve incompetence	Rat, rabbit
	Atrial septal defect	Cat
Myocardial infarction	Sustained atrial pacing	Dog
	Coronary ligation	Dog, pig
	Controlled occlusion— subclavian-to-carotid shunt	Dog
	Coronary embolism	Dog, calf, pig
	Thrombus generation	Dog
Cardiomyopathy and other conditions	Chronic hypoxia	Rat
	Left ventricular Dacron patch	Dog
	Spontaneous cardiomyopathy	Hamster, mouse, cattle, rat, turkey, cat, dog
	Barbiturate overdose	Dog
	Furazolidone cardiomyopathy	Turkey, duckling
	Adriamycin cardiomyopathy	Rat, dog, mouse, pig
	Isoprenaline	Rat
	Noradrenaline	Dog
	Amphetamine	Rat
	Cobalt chloride	Rat, pig
	Vitamin E deficiency	Rat, mouse, calf, lamb
	Alcohol intoxication	Rat
	Coxsackie viral myocarditis	Mouse
	Viral encephalomyocarditis	Mouse
	Altered cardiac development and/or function	Transgenic mice

Modified from Smith HJ, Nuttall A: *Cardiovasc Res* 19:181–186, 1985.

Acute left side heart failure is manifested by pulmonary congestion and edema, whereas chronic left side heart failure is manifested by chronic passive pulmonary congestion, chronic edema, hemosiderosis (“heart failure cells”), and fibrosis. The most common causes are (1) myocardial contractility loss associated with myocarditis, myocardial necrosis, or cardiomyopathy; (2) dysfunction of the mitral or aortic valves; and (3) several congenital heart diseases.

Acute right side heart failure results in acute passive congestion leading to hepatomegaly and splenomegaly, whereas chronic right side heart failure results in hepatic congestion (nutmeg liver) and more severe sodium and water retention than in left side heart failure. Edema is evident predominantly as ventral subcutaneous edema in horses and ruminants (Fig. 10-12), ascites in dogs, and hydrothorax in cats. Causes of right-sided failure include (1) pulmonary hypertension, (2) cardiomyopathy, and (3) disease of the tricuspid and pulmonary valves. (See Chapters 8 and 9 for further details on hepatic and pulmonary lesions, respectively, associated with congestive heart failure.)

567

568

## Pathologic Basis of Veterinary Disease, 4th Edition

---

A wide variety of experimental animal models of heart failure exist ([Table 10-1](#)). The models have been used to develop an understanding of human cardiac diseases.

### 10.1.1.6 CLINICAL DIAGNOSTIC PROCEDURES

The array of diagnostic tools available to the veterinarian to evaluate changes in cases of cardiac disease has grown dramatically in the past decade as many procedures have been adapted from use in human medicine. Procedures include physical examination, radiography, electrocardiology, echocardiography, angiocardiology, and cardiac catheterization. Cardiac damage can be detected by increased activity of serum enzymes and isoenzymes, such as creatine phosphokinase, lactate dehydrogenase, troponin T, and aspartate aminotransferase, which are specifically released from injured cardiac muscle cells. Also, increased plasma concentrations of plasma natriuretic peptides (A type [atrial], B type [brain], and C type) may indicate cardiac disease because these hormones are synthesized by cardiac muscle cells. In research studies of cardiac diseases in animals, endomyocardial biopsies have been used to assess the light microscopic and ultrastructural alterations during the course of the disease.

### 10.1.1.7 EXAMINATION OF THE HEART AT NECROPSY AND TISSUE SAMPLING FOR HISTOPATHOLOGIC EVALUATION

Following the removal of the rib cage and exposure of the thoracic organs, the pericardial sac should be incised and observations made on the presence of pericardial thickening and adhesions and the nature and amount of pericardial fluid present. The heart and lungs should be removed together and examined. The great vessels are transected, and the entire heart is examined to determine its overall shape, size, and color.

The hearts of most animals are dissected to expose the endocardium and the four valves. A systematic approach should be followed; usually the heart is opened in the direction of blood flow with incisions through the right atrium and right ventricle to the right ventricular apex and then along the right ventricular wall adjacent to the interventricular septum into the pulmonary outflow tract. The left side is incised from the atrium to the left ventricular apex to expose the endocardial surfaces and mitral valve; subsequently, the mitral valve leaflet is incised to expose the outflow tract into the aorta. After all observed lesions and the weight of the heart are entered in the written record, the heart is placed in fixative solution.

The hearts of small animals, such as rodents, birds, puppies, and kittens, are often collected and placed intact in the fixative solution.

Other procedures that can be performed on hearts before fixation to quantitate hypertrophy and dilation include measurements of ventricular wall thicknesses, determination of weights of individual cardiac chambers and septum, and measurements of atrioventricular valve ring circumferences.

After fixation for at least 24 hours, tissue samples should be removed from standard sites for histopathologic evaluation ([Fig. 10-14](#)). If gross lesions are apparent, representative samples should be taken of those lesions. In small-sized hearts, the fixed specimen is bisected perpendicular to the long axis of the septum to provide a sample for histopathologic study that includes sections of all four chambers and interventricular and interatrial septa.

Special sampling procedures are available for comprehensive evaluation of the cardiac conduction tissue.

### 10.1.2 DISEASES OF THE HEART

#### 10.1.2.1 CONGENITAL ANOMALIES

The complex events involved in the embryologic development of the heart and great vessels allow substantial opportunities for congenital anomalies to develop. The functional significance of these anomalies varies widely. Animals with the most extreme defects will be unable to survive in utero, and those with the mildest lesions could have no clinical signs of disease during life. However, animals with defects of intermediate severity are most likely to be presented to a veterinarian because of gradually developing signs of cardiac failure, including poor exercise tolerance, cyanosis, and stunted body growth. The most frequently observed cardiovascular anomalies in domestic animals are listed in [Table 10-2](#).

The causes of congenital cardiovascular anomalies are varied. Most animal species have a low background frequency of spontaneous cardiac malformations. In many species, especially in dogs, these defects are heritable and can be attributed to either single or multiple gene effects. Under experimental conditions, cardiovascular congenital defects can be elicited by exposure of pregnant dams to various chemicals and drugs, physical agents, toxins, or nutritional deficiencies. Chemical compounds implicated include thalidomide, ethanol, salicylates, griseofulvin, and cortisone. Prenatal exposure to x-irradiation or fetal hypoxia can induce defects. Maternal nutritional deficiencies of vitamin A, pantothenic acid, riboflavin, or zinc and excess intake of vitamin A, retinoic acid, or copper can result in cardiovascular anomalies in newborn animals.

568

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Sites of the major cardiovascular anomalies in the dog are shown in [Fig. 10-15](#).

10.1.2.1.1

### ANOMALIES FROM FAILURE OF CLOSURE OF FETAL CARDIOVASCULAR SHUNTS

Patent ductus arteriosus is a frequent anomaly in poodle, collie, Pomeranian, Chihuahua, Maltese, English springer spaniel, keeshond, bichon frise, and Shetland sheepdog breeds ([Fig. 10-16](#)). In poodles, it is an inherited lesion. Female dogs have a greater incidence. This vascular channel between the pulmonary artery and aorta allows blood to bypass the lungs during fetal life and normally is converted to the solid ligamentum arteriosum postnatally. It remains patent in dogs with this anomaly. Generally, blood is shunted from the left to the right ventricle, resulting in pulmonary hypertension.

An atrial septal defect could represent the failure of closure of the foramen ovale, which is an interatrial septal shunt that allows blood to bypass the lungs of the fetus, or it can be the result of true septal defects at another site because of faulty development of the interatrial septum ([Fig. 10-17](#)). Dog breeds with greatest frequency of this defect are the boxer, Doberman pinscher, and Samoyed.

**Fig. 10-15 Schematic diagram of the sites of the major cardiovascular anomalies of the dog.** AS, aortic stenosis; ASD, atrial septal defect; PDA, patent ductus arteriosus; PS, pulmonic stenosis; VSD, ventricular septal defect. (Redrawn with permission from School of Veterinary Medicine, Purdue University.)

A ventricular septal defect indicates failure of complete development of the interventricular septum and allows the shunting of blood between the ventricles (Fig. 10-18). The defect occurs in many species and more commonly in the upper, membranous portion of the interventricular septum rather than in the lower, muscular septum. Among breeds of dogs, the greatest frequency has been observed in the English bulldog, English springer spaniel, and West Highland white terrier.

The tetralogy of Fallot is a complicated cardiac anomaly with four lesions (Fig. 10-19). The three primary defects are a ventricular septal defect located high in the septum, pulmonic stenosis (see later discussion), and dextroposition of the aorta (see later discussion). The fourth defect, which develops secondarily, is hypertrophy of the right ventricular myocardium. This complex anomaly is inherited in keeshond dogs and is frequent in English bulldogs. Cyanosis is often an associated clinical sign. The anomaly is one of the most common cardiac abnormalities seen in hearts of human beings (so-called blue babies). By genetic and pathologic studies of keeshond dogs, the basic defect has been determined to be hypoplasia and malpositioning of the conotruncal septum. Wide variability in the severity of the lesions has been observed.

### 10.1.2.1.2

#### ANOMALIES FROM FAILURE OF NORMAL VALVULAR DEVELOPMENT

Pulmonic stenosis has been recognized as a frequently occurring anomaly in dogs and is inherited in such breeds as the beagle, English bulldog, and Chihuahua (Fig. 10-20). Other breeds in which this lesion is frequent are basset hound, boxer, Chow chow, cocker spaniel, Labrador retriever, mastiff, Newfoundland, Samoyed, schnauzer, and terriers. Several types of valvular lesions have been described and include

## Pathologic Basis of Veterinary Disease, 4th Edition

formation of a circumferential band of fibrous or muscular tissue beneath the valve (subvalvular stenosis) or malformation of the valve (valvular stenosis), with a small central orifice in a dome of thickened valvular tissue. Notable concentric hypertrophy (see Myocardial Diseases, Growth Disturbances) of the right ventricle will develop from the resulting pressure overload.

Subaortic stenosis is a cardiac anomaly frequently observed in pigs and dogs. It apparently is inherited in Newfoundland, boxer, and German shepherd dogs (Fig. 10-21). The lesion is also observed in the German shorthair pointer, golden retriever, Great Dane, rottweiler, Samoyed, and bull terrier breeds. In clinical cases, the stenosis is produced by the presence of a thick zone of endocardial fibrous tissue that encircles the left ventricular outflow tract below the valve. In mild cases, often subclinical, the lesion is limited to white nodules on the ventricular septum immediately below the valve. Microscopically the altered endocardial tissue can contain proliferated mesenchymal cells, mucinous ground substance, and foci of metaplastic cartilage. Other cardiac lesions develop as a result of the altered left ventricular outflow; these include left ventricular concentric hypertrophy, disseminated foci of myocardial necrosis, fibrosis in the inner left ventricular wall, and thickening of the walls of intramyocardial arteries.

570

571

**Fig. 10-16 Patent ductus arteriosus, heart, neonatal animal.** Note the prominent ductus arteriosus (*arrow*) between the pulmonary artery (*PA*) and the aorta (*A*) in the undissected (*left*) and dissected vessels (*right*). (Courtesy Dr. D.D. Harrington, School of Veterinary Medicine, Purdue University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

**Fig. 10-17 Atrial septal defect, heart, opened right side, pig.** The prominent opening (*arrow*) low in the atrial septum (AS) and just above the arterioventricular valve is the atrial septal defect. VS, Ventricular septum. (*Courtesy School of Veterinary Medicine, Purdue University.*)

Valvular hematomas (hematocysts) frequently are observed on the atrioventricular valves of postnatal ruminants ([Fig. 10-22, A](#)). These lesions, which generally regress spontaneously by the time the animals are several months of age, do not produce any functional abnormalities. Lesions are bulging, blood-filled cysts, several millimeters in diameter, on the edges of the atrioventricular valves.

Fig. 10-18 **Ventricular septal defect (high defect), heart, opened left side, calf.** Note the large opening in the basal portion of the ventricular septum (*arrow*) immediately below the aortic valve through which the tube has been passed. A, Aorta; LV, left ventricle. (Courtesy Dr. M. D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Valvular lymphocysts may also occur and appear as yellow serum-filled cysts on the atrioventricular valve cusps (Fig. 10-22, *B*).

Other valvular developmental anomalies include endocardial cushion defects (persistent atrioventricular canal) in pigs and cats, mitral dysplasia in cats and dogs, and tricuspid dysplasia in cats and dogs.

Fig. 10-19 **Tetralogy of Fallot, heart, dissected, dog.** Above the large basal ventricular septal defect is an overlying, straddling aorta (A). There is also severe pulmonic stenosis (*arrow*) with massive right ventricular hypertrophy. LV, left ventricle; RV, right ventricle. (Courtesy School of Veterinary Medicine, Purdue University.)

Fig. 10-20 **Pulmonic stenosis, heart, pulmonary artery, dog.** Note the prominent right ventricular (RV) hypertrophy and the white, thick mass of fibrous connective tissue (*arrows*) lining and constricting the outflow tract beneath the pulmonary valve. The pulmonary artery (PA) above the stenotic valve is dilated because the narrowing of the valve lumen forces the blood through the narrow lumen, resulting in a “jetlike” stream of blood that strikes the surface of the pulmonary artery, leading to roughening, deformation, and eventual dilation. (*Courtesy School of Veterinary Medicine, Purdue University.*)

Fig. 10-21 **Subaortic stenosis, heart, opened left side, dog.** A thick, white, broad band of fibrous connective tissue (*arrows*) encircles the left ventricular outflow tract below the aortic valve. The force of the blood ejected through the stenotic lesion is responsible for the “jet lesions” in the overlying aorta (*A*) (*right half*—roughened surface; *left half*—dilation [note the gray area]). (Courtesy College of Veterinary Medicine, University of Illinois.)

571

10.1.2.1.3

### ANOMALIES FROM MALPOSITIONING OF GREAT VESSELS

572

Persistent right aortic arch occurs in dogs; German shepherd, Irish setter, and Great Dane dogs are predisposed (Fig. 10-23). This defect arises because the right fourth aortic arch, rather than the left, develops and ascends on the right side of the midline so that the ligamentum arteriosum forms a vascular ring over the esophagus and trachea. This arrangement eventually results in esophageal obstruction and proximal dilation (megaesophagus) as the animal matures and consumes solid feed.

Transposition of the aorta and pulmonary artery are severe anomalies, of which there are several types.

## Pathologic Basis of Veterinary Disease, 4th Edition

10.1.2.1.4

### OTHER CARDIAC ANOMALIES

Ectopia cordis is the congenital development of the heart at an abnormal site outside of the thoracic cavity. In cattle, cases in healthy adult animals have been described in which the heart was located subcutaneously in the caudoventral neck area.

Endocardial fibroelastosis in animals has been most recognized as a primary cardiac defect in Burmese and Siamese cats. In this heritable disease, the heart has prominent, white, thickened endocardium, especially of the left ventricle, because of the proliferation of fibroelastic tissue (Fig. 10-24).

572

573

**Fig. 10-22 Hematocysts and lymphocysts, calf.** **A**, Valvular hematocyst, heart, opened left side, mitral valve, postnatal calf. A dark, blood-filled cyst protrudes from a cusp of the mitral valve. Arrows indicate chordae tendinae. Hematocysts usually occur in ruminants, do not cause any functional abnormality, and usually regress within a few months of birth. **B**, Valvular lymphocyst, heart. A lymph-filled cyst is on a cusp of the atrioventricular valve. Like hematocysts, lymphocysts usually occur in ruminants, do not cause any functional abnormality, and usually regress within a few months of birth. (**A**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Peritoneopericardial diaphragmatic hernias occur in dogs with incomplete development of the diaphragm. Abdominal viscera can be located in the pericardial sac.

### 10.1.2.2 PERICARDIAL DISEASES

#### 10.1.2.2.1 FLUID ACCUMULATIONS IN THE PERICARDIAL SAC

Hydropericardium is the accumulation of clear to light yellow, watery, serous fluid (i.e., transudate) in the pericardial sac, which becomes distended (Fig. 10-25). In cases associated with vascular injury, such as “mulberry heart disease” (dietary microangiopathy of pigs), a few fibrin strands are present, and the fluid could clot following exposure to air. The pericardial surfaces are smooth and glistening in acute cases, but in chronic cases the epicardium becomes opaque because of mild fibrous thickening and can appear roughened and granular when there is villous proliferation of fibrous tissue, especially over the atria.

573

574

**Fig. 10-23 Persistent right aortic arch, ligamentum arteriosum, megaesophagus, calf.** Because during embryogenesis the aorta was formed from the right aortic arch instead of the left one, the aorta is now on the right. Thus in order for the ligamentum arteriosum (*arrow*) to connect the aorta with the pulmonary artery, it has to pass dorsally over the esophagus and trachea. The ligamentum, together with the aorta and pulmonary artery, form a vascular ring that constricts the esophagus (*E*), which is dilated cranial to the constriction. (Courtesy Dr. S. Snyder, College of Veterinary Medicine, Colorado State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Fig. 10-24 **Subendocardial fibroelastosis, heart, left ventricle, dog.** The endocardium is opaque because increased amounts of collagen and elastic fibers were deposited in the subendocardium secondary to turbulence of blood flow within the ventricles. This dog had a persistent ductus arteriosus. This lesion may have a hereditary basis in Burmese cats and is often a sequela to turbulence within ventricles in cardiac disease. (Courtesy College of Veterinary Medicine, University of Illinois.)

Fig. 10-25 **Hydropericardium, pericardial sac, pig.** The thin-walled pericardial sac contains serous fluid that has accumulated secondary to alterations in hydrostatic pressure between the pericardial cavity, circulatory system, and lymphatic system. (Courtesy College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Hydropericardium occurs in those diseases that have generalized edema. Thus ascites and hydrothorax often occur concurrently with hydropericardium. Congestive heart failure is an important mechanism of hydropericardium and is usually due to primary myocardial, valvular, congenital, or neoplastic diseases. Common specific diseases include dilated cardiomyopathy of dogs and cats and “ascites syndrome” of poultry. Hydropericardium can also accompany pulmonary hypertension (e.g., “brisket disease” or “high-altitude disease” of cattle), renal failure, and hypoproteinemia from various chronic debilitating diseases. Hydropericardium can also occur in various systemic diseases with vascular injury, such as septicemia in pigs, “heartwater” (*Cowdria ruminantium* infection) in small ruminants, African horse sickness, and bovine ephemeral fever.

Hydropericardium of rapid onset and of sufficient volume leads to development of cardiac tamponade or compression, which interferes with cardiac filling (especially of the atria) and venous return to the heart. In cases with slow development, stretching of the pericardium allows accumulation of a large volume of fluid without tamponade. Hydropericardium can be reversed if the underlying cause is removed. However, many cases are associated with progressive cardiac diseases, and death is the outcome.

Hemorrhagic pericardial effusion of unknown cause is frequently seen in dogs. Large or giant breeds, such as the Great Dane, Saint Bernard, Great Pyrenees, German shepherd, and golden retriever are most often affected. The preferred treatment for the condition is pericardectomy. Similar effusions have occurred in dogs with cardiac hemangiosarcomas and heart base tumors, common cardiac neoplasms in this species. These diseases will be discussed later in this chapter.

574

575

**Fig. 10-26 Hemopericardium (cardiac tamponade), right atrial hemangiosarcoma. heart, dog.** The pericardium is distended and dark blue because it contains whole blood secondary to rupture of an atrial hemangiosarcoma. Hemopericardium can cause death if it is sudden and is of sufficient volume to compress the heart and thus reduce cardiac output, a condition known as cardiac tamponade. On clinical examination, heart sounds are muffled. (*Courtesy College of Veterinary Medicine, University of Illinois.*)

**Fig. 10-27 Hemopericardium, heart, dog.** The pericardial sac is filled with clotted blood. Hemorrhage into a body cavity results in pooling of coagulated or noncoagulated blood within that cavity.  
(Courtesy Dr. D.A. Mosier, College of Veterinary Medicine, Kansas State University.)

Hemopericardium is an accumulation of whole blood in the pericardial sac (Figs. 10-26 and 10-27). Death often occurs suddenly from cardiac tamponade, a condition with compression of the heart caused by blood or fluid accumulation in the pericardial sac leading to reduced cardiac output. Bleeding into the pericardial sac can result from spontaneous atrial rupture in dogs, atrial rupture in dogs with hemangiosarcoma, rupture of the intrapericardial aorta in horses, or as a complication of intracardiac injections.

### 10.1.2.2.2

#### METABOLIC ALTERATIONS

Serous atrophy of fat is readily identified by the gray gelatinous appearance of epicardial fat deposits (Fig. 10-28). Healthy animals normally have abundant white or yellow epicardial fat deposits, especially along the atrioventricular junction. Microscopically, lipocytes are atrophic and edema fluid is present in interstitial tissue. Serous atrophy of epicardial fat occurs rapidly during anorexia, starvation, or cachexia as fat is catabolized to maintain energy balance.

Epicardial mineralization (cardiac calcinosis) is a striking lesion of certain inbred strains of mice (Fig. 10-29, A and B). In this inherited disorder, white, firm, mineralized plaques are present, especially over the right ventricular epicardium. The lesion, arising by dystrophic calcification, does not tend to cause cardiac dysfunction.

**Fig. 10-28 Seros atrophy of fat, heart, epicardium, cow.** The epicardial fat deposits are gray and gelatinous (*arrows*), indicating that fat has been catabolized, for example as in the early stages of starvation. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Urate deposits on the pericardium occur in birds and snakes with visceral gout. The affected serosal surface appears thickened and white from the accumulations of uric acid crystals ([Fig. 10-30](#)).

### 10.1.2.2.3

## INFLAMMATION

The various portals of entry and defense mechanisms involved in pericardial inflammation are summarized in [Box 10-1](#) and [Box 10-2](#). Fibrinous pericarditis, the most common type of pericardial inflammation in animals, is usually the result of hematogenously spread infection. Specific diseases with this lesion include those in cattle (pasteurellosis, blackleg, coliform septicemias, and sporadic bovine encephalomyelitis), pigs (Glasser's disease, streptococcal infections, pasteurellosis, enzootic mycoplasmal pneumonia, and salmonellosis), horses (streptococcal infections), and birds (psittacosis). Grossly, both the visceral and parietal pericardial surfaces are covered by variable amounts of yellow fibrin deposits, which can result in adherence between the parietal and visceral layers. When the pericardial sac is opened upon necropsy, these attachments are torn away (so-called bread-and-butter heart) ([Fig. 10-31](#)). Microscopically an eosinophilic layer of fibrin with admixed neutrophils lies over a congested pericardium ([Fig. 10-32](#)).

The outcome of fibrinous pericarditis varies. Early death is frequent because many of these lesions result from infection by highly virulent bacteria and concurrent septicemia. When survival is prolonged, fibrous adhesions form between the pericardial surfaces after fibrous organization of the exudate.

Suppurative pericarditis is seen mainly in cattle as a complication of traumatic reticuloperitonitis ("hardware disease"). Foreign bodies, such as nails or pieces of wire that accumulate in the reticulum, occasionally penetrate the reticular wall and diaphragm, enter the adjacent pericardial sac, and introduce infection. Some affected cattle survive for weeks to months until death ensues from congestive heart failure and septicemia. Grossly the pericardial surfaces are notably thickened by white, often rough, shaggy-appearing masses of fibrous connective tissue that enclose an accumulation of white to gray, thick, foul-smelling, purulent exudate ([Fig. 10-33](#)).

Fig. 10-31 **Fibrinous pericarditis, heart, epicardium, horse.** The epicardium is covered dorsally by a thick, yellow layer of fibrin (*arrows*) and ventrally by granulation tissue (finely granular surface), thus indicating the chronicity of the inflammatory process. The apposing parietal pericardium (not shown) was also covered with fibrin. This lesion commonly occurs in horses with *Streptococcus zooepidemicus* septicemia causing vasculitis. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 10-32 **Fibrinous pericarditis, heart, epicardium, pig.** Note eosinophilic fibrin deposits (*left*) on the epicardial surface (*E*). This lesion commonly occurs with septicemias of bacteria that cause vasculitis. H&E stain. (Courtesy School of Veterinary Medicine, Purdue University.)

Fig. 10-33 **Chronic suppurative pericarditis, traumatic reticuloperitonitis (“hardware disease”), heart, pericardial sac (opened), cow.** The exposed epicardial and parietal surfaces are notably thickened by fibrous connective tissue and covered by a fibrinopurulent exudate. On clinical examination, heart sounds are muffled. *P*, Reflected parietal pericardium. (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

Constrictive pericarditis is a chronic inflammatory lesion of the pericardium accompanied by extensive fibrous proliferation and eventual formation of fibrous adhesions between the surfaces of the visceral and parietal pericardium. The condition is seen in some cases of suppurative pericarditis in cattle. Severe lesions obliterate the pericardial sac and constrict the heart with fibrous tissue and can interfere with cardiac filling and thus cardiac output. Compensatory myocardial hypertrophy can result in diminished ventricular chamber volumes and contribute to the eventual development of congestive cardiac failure.

### 10.1.2.3 ENDOCARDIAL DISEASES

#### 10.1.2.3.1 DEGENERATION

Endocardial mineralization and endocardial fibrosis can occur singly or together. Mineralization occurs from intake of excessive amounts of vitamin D and from intoxication by calcinogenic plants (*Cestrum diurnum*, *Trisetum flavescens*, *Solanum malacoxylon*, *Solanum torvum*) that contain vitamin D analogs. These plant-induced syndromes of cattle have been called by different names in various areas of the world, such as “Manchester wasting disease” in Jamaica, “enzootic calcinosis” in Europe, “naahelu disease” in Hawaii, “enteque seco” in Argentina, and “espichamento” in Brazil. Multiple, large, white, rough, firm plaques of mineralized fibroelastic tissue are present in the endocardium and intima of large elastic arteries. Fibrosis, with or without mineralization, occurs in chronically dilated hearts, in hearts of debilitated cattle with Johne's disease (Fig. 10-34), in dogs with healed lesions of left atrial ulcerative endocarditis associated with a prior uremic episode (Fig. 10-35), and in the so-called jet lesions produced by the trauma of refluxed blood in valvular insufficiencies.

**Fig. 10-34 Endocardial mineralization, Johne's disease, heart, left atrial endocardium, cow.** The left atrial (LA) endocardium is white, thick, and wrinkled from mineralization. (Courtesy School of Veterinary Medicine, Purdue University.)

**Fig. 10-35 Ulcerative endocarditis (uremia), heart, endocardium of left atrium, dog.** Note the white-red, thick, wrinkled area (*arrows*) of endocarditis, mineralization, and fibrous tissue (scar) formation caused by uremia in this dog with chronic renal failure. (Courtesy Dr. K. Read, College of Veterinary Medicine, Texas A&M University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Valvular endocardiosis is an important age-related cardiac disease of middle-aged to old dogs, especially small and toy breeds, associated with degeneration of valvular collagen. Other names for this disease include valvular fibrosis and myxomatous or mucoid valvular degeneration. This disease, the most common cause of congestive heart failure in old dogs, appears to have a polygenic basis. Males of certain breeds are most frequently affected. The cavalier King Charles spaniel breed has a unique susceptibility, with more than 50% prevalence by 4 years of age and 100% prevalence by 10 years of age. Other breeds with high incidence include the cocker spaniel, beagle, dachshund, poodle, Pomeranian, schnauzer, Chihuahua, Doberman pinscher, fox terrier, Boston terrier, Pekingese, deerhound, and wolfhound. Lesions occur most frequently on the mitral valve, less commonly on the tricuspid, and infrequently on the aortic and pulmonary valves. Affected valves are shortened and thickened (nodular), either focal or diffusely, and appear smooth and shiny (Fig. 10-36, A and B) rather than rough and granular as is usual in cases of valvular endocarditis. These lesions result in valvular insufficiency with subsequent atrial dilation and development of atrial “jet lesions.” The jet lesion is a raised, rough, firm streak of endocardial fibrosis resulting from long-term trauma by a jet of blood leaking through the damaged valve in the closed position. Other complications of valvular endocardiosis include occasional rupture of the chordae tendineae and occasional splitting or rupture of the left atrial wall. Microscopically the thickened valves

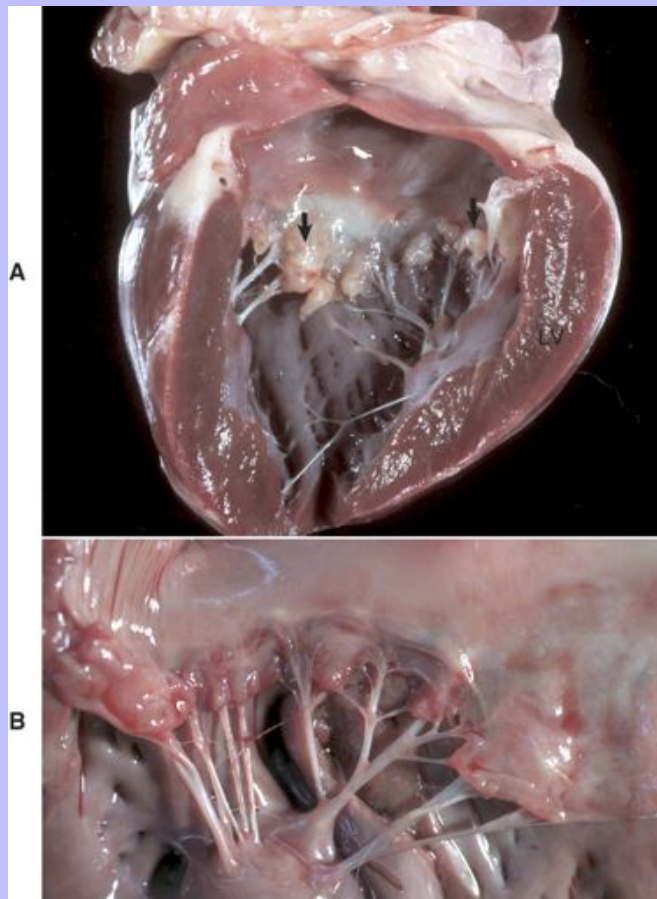

578

579

## Pathologic Basis of Veterinary Disease, 4th Edition

have notably increased fibroblastic proliferation and deposition of acid mucopolysaccharides (Fig. 10-37). Frequent accompanying myocardial alterations include arteriosclerosis of intramyocardial arteries and multifocal myocardial necrosis and fibrosis.

**Fig. 10-36 Valvular endocardiosis, left atrioventricular valve, heart, dog.** **A**, The cusps of the mitral valve are thickened by white, smooth nodules (*arrows*). LV, Left ventricular free wall. **B**, Note the characteristic smooth and shiny (endocardial) surface of the valve and nodules. This differentiates endocardiosis from the rough and granular surface of chronic bacterial endocarditis. The pink staining of the valve is caused by postmortem inhibition of hemoglobin. ### 10.1.2.3.2

#### CIRCULATORY DISTURBANCES

Atrial thrombosis is a frequent lesion in aged Syrian hamsters and in certain strains of mice and has been found in the failing hearts of dogs and cats with idiopathic cardiomyopathies. In affected hamsters and mice, the atria are swollen, firm, mottled and have gray-to-tan, laminated masses of fibrin. Fibroblastic organization occurs rapidly in the thrombi. Etiologic factors include aging, and genetic and dietary influences. Susceptible strains fed a thrombogenic diet (high fat, low protein, and hypolipotropic) have a high incidence of atrial thrombosis.

**Fig. 10-37 Valvular endocardiosis, cusp of right atrioventricular valve, heart, dog.** The valve is thickened and nodular from an increase in myxomatous tissue supported by a fibrous stroma. H&E stain. (Courtesy School of Veterinary Medicine, Purdue University.)

### 10.1.2.3.3

#### INFLAMMATION

The various portals of entry and defense mechanisms involved in endocardial inflammation are summarized in [Box 10-1](#) and [Box 10-2](#). Endocarditis is usually the result of bacterial infections, except for lesions produced by migrating *Strongylus vulgaris* larvae in horses and an occasional case of mycotic infection. The lesions are often very large by the time of death and are present on the valves (valvular endocarditis), although some lesions extend to the adjacent wall (mural endocarditis). Grossly the affected valves have large, adhering, friable, yellow-to-gray masses of fibrin termed “vegetations,” which can largely occlude the valvular orifice ([Fig. 10-38](#)). In chronic lesions, the fibrin deposits are organized by fibrous connective tissue to produce irregular nodular masses termed “verrucae” (wartlike lesions). Microscopically the lesion consists of accumulated layers of fibrin and numerous embedded bacterial colonies underlain by a zone of infiltrated leukocytes and granulation tissue ([Fig. 10-39](#)). Relative frequency of valvular involvement with endocarditis in animals is mitral > aortic > tricuspid > pulmonary.

The pathogenesis of endocarditis is complicated and frequently incompletely understood, but the components of Virchow's triad in thrombogenesis—endothelial injury, turbulence, and hypercoagulability—are involved. Affected animals often have preexisting extracardiac infections, such as gingivitis or dermatitis, that have resulted in one or more bouts of bacteremia. Turbulent intracardiac blood flow associated with congenital anomalies, or the presence of intracardiac devices, such as catheters, is contributory to initiation of the lesion. Focal trauma-induced endothelial disruption on the surface of the normally avascular valves allows bacteria to adhere, proliferate, and initiate an inflammatory reaction that results in subsequent deposition of masses of fibrin. Bacteria frequently recovered from the vegetative lesions are *Arcanobacter pyogenes* in cattle, *Streptococcus* spp. and *Erysipelothrix rhusiopathiae* in pigs (Fig. 10-40), and *Streptococcus* spp. and *Escherichia coli* in dogs and cats. Death is the result of cardiac failure from valvular dysfunction or the effects of bacteremia. In some animals, septic emboli lodge in organs such as the heart and kidneys, leading to infarction and localized inflammation or abscess formation.

579

580

**Fig. 10-38 Vegetative valvular endocarditis, tricuspid valve, heart, calf.** Multiple, large, raised, friable, yellow-red thrombotic masses are attached to cusps of the tricuspid valve. The roughened and granular surface of the valve leaflets is attributable to fibrin, platelets, and trapped bacteria (Fig. 10-39) and erythrocytes. This calf had an indwelling jugular catheter, presumed to be the source of the infection. (Courtesy College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Ulcerative endocarditis of the left atrium is a distinctive red hemorrhagic lesion acutely associated with acute renal insufficiency in dogs. Grossly, after the initial ulcer heals, the area is replaced by raised, white plaques of fibrous and mineralized tissue.

Major cardiac valvular lesions are summarized in [Fig. 10-41](#).

### 10.1.2.4 MYOCARDIAL DISEASES

#### 10.1.2.4.1 GROWTH DISTURBANCES

Hypertrophy of the myocardium represents an increase in muscle mass, the result of an increase in size of cardiac muscle cells. Hypertrophy is generally secondary and is the result of a compensatory response to increased workload; it is usually reversible on removal of the cause. However, primary hypertrophy also occurs, as in cats and dogs with idiopathic hypertrophic cardiomyopathy (see later discussion) and is not reversible. Two anatomic forms of hypertrophy are recognized. Eccentric hypertrophy results in a heart with enlarged ventricular chambers and walls of normal to somewhat decreased thickness; it is produced by lesions that increase blood volume load, such as valvular insufficiencies and septal defects. In concentric hypertrophy the heart is characterized by small ventricular chambers that have thick walls; it results from lesions that increase pressure load, such as valvular stenosis, systemic hypertension, and pulmonary disease. Some cats with hyperthyroidism have a cardiac hypertrophy that is mediated by enhanced production of myocardial contractile proteins under the influence of increased concentration of circulating thyroid hormones ([Fig. 10-42](#)). The hypertrophy is reversible on return to euthyroidism.

## Pathologic Basis of Veterinary Disease, 4th Edition

10.1.2.4.1.1

### Stages of Myocardial Hypertrophy

Three stages of myocardial hypertrophy are recognizable: (1) initiation, (2) stable hyperfunction, and (3) deterioration of function associated with degeneration of hypertrophied myocytes. Microscopically, in myocardial hypertrophy, the myocytes are enlarged and have large nuclei (Fig. 10-43).

**Fig. 10-42 Left ventricular hypertrophy, hyperthyroidism, heart, bisected, cat.** Note prominent thickening of the left ventricular (LV) free wall. The ventricular septum (VS) is also thickened. (Courtesy School of Veterinary Medicine, Purdue University.)

10.1.2.4.1.1.1

### Right ventricular hypertrophy

Diseases that produce right ventricular hypertrophy include dirofilariasis (Fig. 10-44) and congenital pulmonic stenosis in dogs, “brisket disease” (“high-altitude disease”) in cattle, and chronic alveolar emphysema (“heaves”) in horses. Cattle maintained under the hypoxic conditions that exist at altitudes above 7000 feet above sea level develop pulmonary hypertension and subsequent right side heart failure with subcutaneous edema, chronic passive congestion of the liver (nutmeg liver), and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

right ventricular hypertrophy. Exposure to certain poisonous plants (*Oxytropis* spp. and *Astragalus* spp.) increases the severity of the disease.

In the United States, dirofilariasis (heartworm disease) may occur in 35% to 45% of dogs and 2% of cats in areas of high infection rates, such as within 150 miles of the Atlantic and Gulf coasts from Texas to New Jersey and along the Mississippi River and its major tributaries. The extent of cardiac alterations is related to the numbers of adult parasites present. Initially the parasites accumulate in the pulmonary arteries (Figs. 10-45 and 10-46), and as the numbers increase, they are present in the right ventricle, then in the right atrium, and finally may occupy the vena cavae. Pulmonary hypertension results from vascular blockage and pulmonary vascular lesions produced by the parasites and right ventricular hypertrophy follows. Right side heart failure may eventually develop.

582

583

Dogs with massive adult parasite loads may suffer acute collapse from caval syndrome, characterized by shock, intravascular hemolysis, and hepatic and renal failure.

**Fig. 10-43 Hypertrophic cardiomyopathy, myocyte hypertrophy, heart, myocardium, cat.** Cardiac myocytes are hypertrophied, and there is an increase in interstitial fibroblasts. H&E stain. (Courtesy School of Veterinary Medicine, Purdue University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

10.1.2.4.1.1.2

### Left ventricular hypertrophy

Left ventricular hypertrophy occurs in dogs with congenital subaortic stenosis, in cats with hyperthyroidism, and in dogs and cats with systemic hypertension. Systemic hypertension tends to be associated with hyperthyroidism and chronic renal failure in cats, and with chronic renal failure and hyperadrenocorticism in dogs. Affected animals may have ocular lesions secondary to damage to retinal vessels.

10.1.2.4.1.1.3

### Biventricular hypertrophy

Biventricular hypertrophy can occur with hypertrophic cardiomyopathy and various congenital cardiac anomalies. Eccentric hypertrophy develops in the late stages of diseases that initially cause concentric hypertrophy as cardiac dilation is superimposed.

The appearance of cardiac hypertrophy and dilation is summarized in [Fig. 10-47](#).

**Fig. 10-47 Schematic diagram of the types of myocardial hypertrophy and dilation.** Left lateral view and midventricular cross section (not drawn to same scale). A, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle. (Redrawn with permission from School of Veterinary Medicine, Purdue University.)

583

10.1.2.4.2

### INFILTRATION

584

Fatty infiltration is the presence of increased numbers of lipocytes interposed between myocardial fibers. The lesion is associated with obesity and appears as abundant epicardial and myocardial deposits of adipose tissue.

10.1.2.4.3

### DEGENERATION

Fatty degeneration (fatty change) is the accumulation of abundant lipid droplets in the sarcoplasm of myocytes. Grossly the myocardium is pale and flabby. Microscopically, affected myocytes have numerous variably sized spherical droplets that appear as empty vacuoles in paraffin sections but stain positively for lipids with lipid-soluble stains in frozen sections. This lesion occurs with systemic disorders, such as severe anemia, toxemia, and copper deficiency, but is seen much less often in the heart than in the liver and kidneys.

Hydropic degeneration, a distinctive microscopic alteration in cardiac muscle cells, is associated with chronic administration of anthracyclines, a group of antineoplastic drugs. Chronic passive congestion with ascites and cardiac dilation may result (Figs. 10-48 and 10-49). Affected fibers have extensive vacuolization of sarcoplasm that is initiated by distention of elements of sarcoplasmic reticulum and, eventually, ends in lysis of contractile material (Figs. 10-50 and 10-51).

Lipofuscinosis (brown atrophy) of the myocardium occurs in aged animals and in animals with severe cachexia, but it also has been described as a hereditary lesion in healthy Ayrshire cattle. Severely affected hearts appear brown and microscopically have clusters of yellow-brown granules at the nuclear poles of myocytes. These granules represent intralysosomal accumulation of membranous and amorphous debris (residual bodies).

Myofibrillar degeneration (myocytolysis) represents a distinctive sublethal injury of cardiac muscle cells. Affected fibers have pale eosinophilic sarcoplasm and lack cross striations. Ultrastructurally, myofibrils have a variable extent of dissolution (myofibrillar lysis). This lesion has been described in furazolidone cardiotoxicity in birds (Figs. 10-52 and 10-53) and potassium deficiency in rats.

10.1.2.4.4

### NECROSIS AND MINERALIZATION

Myocardial necrosis can result from a number of causes, including nutritional deficiencies, chemical and plant toxins, ischemia, metabolic disorders, heritable diseases, and physical injuries (Box 10-3). From this large list of causes of myocardial injury, some of the most frequently observed current examples are ionophore toxicity in horses and ruminants, vitamin E-selenium deficiency in the young of all species, “heart-brain syndrome” of dogs (Fig. 10-54), anthracycline toxicity in dogs, and gossypol toxicosis in pigs. In various localized areas throughout the world, numerous deaths in ruminants have resulted from consumption of poisonous plants, such as *Acacia georginae* and *Dichapetalum cymosum*.

### PHYSICAL INJURIES AND SHOCK

Central nervous system lesions and trauma ("heart-brain syndrome"), gastric dilation and volvulus, stress, overexertion, electrical defibrillation, hemorrhagic shock

**Fig. 10-53 Myofibrillar lysis, furazolidone cardiotoxicity, heart, ventricular myocardium, duckling.** Affected myocytes have extensive dissolution of myofibrils with scattered free myofilaments and dense clumps of Z-band material (*arrowheads*). Other organelles appear normal. TEM. Uranyl acetate and lead citrate stain. (*Courtesy School of Veterinary Medicine, Purdue University.*)

Cardiotoxicity has emerged as a significant clinical entity in veterinary medicine in recent years with the growing use of antineoplastic drugs in small animal practice and the widespread use of growth promotants in ruminants (Fig. 10-55). The mechanisms of cardiotoxicities include (1) exaggerated pharmacologic action of drugs acting on cardiovascular tissues, (2) exposure to substances that depress myocardial function, (3) direct injury of cardiac muscle cells by chemicals, and (4) hypersensitivity reactions.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Grossly, affected areas appear pale initially, and some progress to prominent yellow to white (Fig. 10-55), dry areas made gritty by dystrophic mineralization. The lesions are focal, multifocal, or diffuse. The most frequent sites of focal lesions are the left ventricular papillary muscles and the subendocardial myocardium, especially when such lesions are related to transient reduction of vascular perfusion. These lesions can be overlooked at necropsy unless multiple incisions are made in the ventricular myocardium. In diseases with diffuse cardiac necrosis, such as white muscle disease of calves and lambs due to selenium–vitamin E deficiency, the discrete white lesions can be readily observed on the epicardial and endocardial surfaces (Fig. 10-56, A and B).

586

587

Nation, Animal Pathology Services; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Microscopically the appearance depends on the age of the lesions. Fibers in areas of recent necrosis often appear swollen and hypereosinophilic (hyaline necrosis). Striations are indistinct, and nuclei are pyknotic. Necrotic fibers often have scattered basophilic granules (Fig. 10-57) that represent calcified mitochondria and can be confirmed by electron microscopy (Fig., 10-58). In a second pattern of necrosis, affected myocytes have a “shredded” appearance because of hypercontraction and the formation of multiple transversely oriented bars of disrupted contractile material (often termed contraction band necrosis) (Fig. 10-59). A third pattern is seen in necrotic myocytes in large areas of ischemic necrosis (infarcts). These myocytes have features of coagulation necrosis and have relaxed rather than hypercontracted contractile elements.

**Fig. 10-57 Acute myocardial necrosis with mineralization, minoxidil cardiotoxicity, heart, ventricular myocardium, pig.** The darker red myocytes are necrotic, and some are mineralized (purplish areas). H&E stain. (Courtesy School of Veterinary Medicine, Purdue University.)

Within 24 to 48 hours after injury, necrotic areas are infiltrated by inflammatory cells, mainly macrophages and a few neutrophils; these phagocytose and lyse the necrotic cellular debris (Fig. 10-60). In early stages of healing of necrosis, it is often difficult to distinguish the lesions from those found in some types of myocarditis (see later discussion). Later, when necrosis has progressed somewhat, lesions consist of persistent stromal tissue (interstitial fibroblasts, collagen, and capillaries) and empty “tubes” of basal laminae formerly occupied by necrotic myocytes (see Chapter 15). The healing phase is characterized by proliferation of connective tissue cells (fibroblasts) and by deposition of connective tissue products (collagen and elastic tissue and acid mucopolysaccharides). Grossly, these areas with healing of myocardial necrosis appear as white, firm, contracted scars.

587

588

Fig. 10-58 **Myocardial necrosis, monensin toxicosis, necrotic myocyte, heart, longitudinal section, calf.** The necrotic myocyte (*center*) has disrupted myofibrils, damaged mitochondria with matrical densities, and several invading macrophages (*M*). *F*, Fibrin. TEM. Uranyl acetate and lead citrate stain. (Courtesy School of Veterinary Medicine, Purdue University.)

Fig. 10-59 **Myocardial necrosis, electric shock overdose by defibrillator, heart, dog.** The dark shredded segments of myocytes are due to acute contraction band necrosis. The time interval between defibrillation and the fixation of the heart was 24 hours. Plastic-embedded, toluidine blue–stained section. (Courtesy School of Veterinary Medicine, Purdue University.)

The outcome of myocardial necrosis varies depending on the extent of the damage:

## Pathologic Basis of Veterinary Disease, 4th Edition

---

1. Many animals die unexpectedly of acute cardiac failure if the myocardial damage is extensive.
2. Early deaths from necrosis-related arrhythmias also occur when cardiac conduction is disrupted.
3. Some cases eventually develop cardiac decompensation and die with cardiac dilation, scarring, and lesions of chronic congestive failure.

Hearts with minimal damage have only microscopically detectable myocardial fibrosis when death eventually occurs from other diseases.

Myocardial mineralization is a prominent feature in several diseases, such as hereditary calcosinosis in mice, cardiomyopathy in hamsters, vitamin E–selenium deficiency in sheep and cattle (Fig. 10-62), vitamin D toxicity in several species, calcinogenic plant toxicosis in cattle (“Manchester wasting disease”), and spontaneous myocardial calcification in aged rats and guinea pigs.

**Fig. 10-60 Myocardial necrosis, monensin toxicosis, heart, section of myocardium, calf.** Necrotic myocyte has disrupted contractile material invaded by a macrophage (M). The basal lamina of the necrotic myocyte is noted by arrowheads. TEM. Uranyl acetate and lead citrate stain. (Courtesy School of Veterinary Medicine, Purdue University.)

Fig. 10-61 **Healing, postmyocardial necrosis, heart, ventricle, dog.** The necrotic myocytes have been removed by phagocytosis by macrophages (not seen here), and the area is now undergoing fibrosis. H&E stain. (Courtesy College of Veterinary Medicine, University of Illinois.)

10.1.2.4.5

### CARDIOMYOPATHIES

Primary and secondary cardiomyopathies ([Table 10-3](#)) represent important generalized myocardial diseases of either idiopathic or known causation.

588

**Fig. 10-62 Calcification, selenium–vitamin E deficiency, myocardial necrosis, heart, right ventricle, lamb.** The multiple white subendocardial lesions are areas of calcified necrotic cardiac myocytes. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Primary or idiopathic cardiomyopathies are progressive cardiac diseases. These diseases affect cats, dogs, cattle, rats, mice, hamsters, turkeys, and several wild animal species and resemble some diseases of human beings. These diseases are divided into three morphologic types: hypertrophic, dilated, and restrictive cardiomyopathies.

Hypertrophic cardiomyopathy occurs frequently in cats, especially in middle-aged males (1 to 3 years old), and is seen infrequently in dogs, usually affecting males of large breeds. Cats usually have congestive heart failure, and approximately 10% to 20% have posterior paresis from concurrent thromboembolism of the caudal abdominal aorta (“saddle thrombosis”) secondary to left atrial thrombosis. The occurrence of clusters of cases in Persians, American shorthairs, and Maine coon cat breeds suggests heritability of the disease in some cases. Some dogs die unexpectedly as the only clinical expression of the disease. This clinical presentation also is often seen in humans with the disease. In both cats and dogs, the hearts are enlarged and have prominent hypertrophy of the left ventricle and interventricular septum (Fig. 10-63, A and B). The left ventricular cavity is small and the left atrium is dilated. In a few cases, the interventricular septum is disproportionately hypertrophied in relation to the remainder of the

## Pathologic Basis of Veterinary Disease, 4th Edition

myocardium. Microscopically the lesions of the myocardium are prominent disarrays or disorganizations	589
of myocytes, with interweaving rather than parallel arrangement of fibers (Fig. 10-64). Myocyte	590
hypertrophy, various degenerative alterations in myocytes, and interstitial fibrosis also are present.	

Table 10-3 Cardiomyopathies in Animals

### PRIMARY CARDIOMYOPATHIES (IDIOPATHIC)

Hypertrophic: cat, dog, rat, pig

Dilated (congestive): cat, dog, hamster, turkey, pig, cow

Restrictive: cat

### SECONDARY CARDIOMYOPATHIES (SPECIFIC HEART MUSCLE DISEASES)

Heritable (known or suspected): hereditary cardiomyopathy of hamsters, mice, rats, turkeys, and cattle; Duchenne's type, x-linked muscular dystrophy of golden retriever dogs with dystrophin deficiency; glycogenoses

Nutritional deficiencies: see list in Box 10-3; other examples include taurine deficiency in cats and foxes

Toxic: see list in Box 10-3; other examples include anthracycline toxicity, furazolidone toxicity, NaCl toxicity

Physical injuries and shock: see list in Box 10-3

Endocrine disorders: hyperthyroidism, acromegaly (hypersomatotropism), hypothyroidism, glucocorticoid excess, functional pheochromocytoma, diabetes mellitus

Infections: see list in Box 10-6

Neoplastic infiltration: malignant lymphoma

Systemic hypertension in cats: spontaneous or associated with chronic renal disease, hyperthyroidism, diabetes mellitus, acromegaly, primary aldosteronism

Fig. 10-63 **Hypertrophic cardiomyopathy, heart, cat.** **A**, Note the thickened left ventricular wall (LV). **B**, The thickened left ventricular free wall and septum have markedly reduced the lumen of the left ventricle (LV). Fig. 10-64 **Hypertrophic cardiomyopathy, heart, ventricular myocardium, cat.** Cardiac myocytes are hypertrophied, and there is an increase in interstitial fibroblasts. H&E stain. (Courtesy School of Veterinary Medicine, Purdue University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Dilated or congestive cardiomyopathy is an important cause of congestive heart failure in cats and dogs. Many affected cats and some dogs have low tissue concentrations of taurine, and supplementation of cats with taurine has reversed the clinical signs of cardiac failure. Routine taurine supplementation of feline commercial diets has resulted in a dramatic reduction in cases of dilated cardiomyopathy. Taurine-deficient foxes also develop cardiac failure. Cattle with dilated cardiomyopathy in Switzerland and Japan have an autosomal recessive mode of inheritance.

Affected cats often are middle-aged males, and affected dogs often are males of large breeds such as Doberman pinschers, Portuguese water dogs, Dalmatians, Scottish deerhounds, Irish wolfhounds, Saint Bernards, Afghan hounds, Newfoundlands, Old English sheepdogs, Great Danes, and boxers, although smaller breeds, such as English cocker spaniels, may be affected. The disease often has a familial pattern in the affected breeds and appears to be inherited as an autosomal recessive or x-linked recessive trait. Some cats also develop aortic thromboembolism. At necropsy, lesions of congestive heart failure are present and the hearts are rounded because of biventricular dilation (Figs. 10-65 and 10-66). The dilated cardiac chambers often have a diffusely white, thickened endocardium. Microscopic and ultrastructural alterations are nonspecific, can be either mild or absent, and may include interstitial fibrosis and fatty infiltration and changes of myocyte degeneration, including the occurrence of so-called attenuated wavy fibers.

**Fig. 10-65 Dilated (congestive) cardiomyopathy, heart, left ventricle (LV) and right ventricle (RV), dog.** Biventricular dilation has resulted in the heart having a double apex. (Courtesy Dr. T. Boosinger, College of Veterinary Medicine, Auburn University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Restrictive cardiomyopathy occurs infrequently. It occurs in cats as one of two types of endocardial lesions that result in impaired ventricular filling. In one type, the left ventricular endocardium has diffuse notable fibrosis. Available evidence suggests that the fibrotic lesion is preceded by endomyocarditis. The second type results from excessive moderator bands that traverse the left ventricular cavity. Other examples of restrictive cardiomyopathy in animals include endocardial fibrosis in certain strains of aged rats and congenital endocardial fibroelastosis in Burmese cats (Fig. 10-24).

Secondary cardiomyopathies (Table 10-3) (also termed specific heart muscle diseases) are generalized myocardial diseases of known cause.

Our understanding of the molecular mechanisms of the hereditary cardiomyopathies is developing rapidly. In human patients with familial hypertrophic cardiomyopathy inherited in an autosomal dominant manner, a variety of single-gene mutations have been documented. The mutations affect genes that encode sarcomeric proteins of cardiac myocytes. Altered cardiac proteins include cardiac  $\beta$ -myosin heavy chain, cardiac troponin T, cardiac troponin I,  $\alpha$ -tropomyosin, actin, ventricular myosin essential light chain, ventricular myosin regulatory light chain, and cardiac myosin-binding protein C. It remains unclear how these mutant proteins result in functional and structural alterations of cardiac muscle cells. However, recent studies suggest that shortening of telomeres (structures that cap the ends of chromosomes) triggers apoptosis of cardiac muscle cells and may explain the end-stage finding of myocardial fibrosis in heart failure of various causes including cardiomyopathy. It is expected that similar gene mutations and altered proteins will be discovered in the various heritable cardiomyopathies of animals.

590

591

**Fig. 10-66 Dilated cardiomyopathy (congestive cardiomyopathy), heart, ventricles, cross section, dog.** The left ventricle (LV) and right ventricle have thin walls, dilated chambers, and white fibrotic endocardium. (Courtesy Dr. Y. Niyo, College of Veterinary Medicine, Iowa State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Also, a portion of cases of dilated cardiomyopathy in human patients appears to be inherited. In these patients, alterations in several myocytic proteins, including dystrophin, actin, desmin, troponin T,  $\beta$ -myosin heavy chain, lamin, and taffazin, and alterations in the cardiac calcium regulating protein phospholamban have been documented.

The various portals of entry and defense mechanisms involved in myocardial inflammation are summarized in [Box 10-1](#) and [Box 10-2](#). Myocarditis generally is the result of infections spread hematogenously to the myocardium and occurs in various systemic diseases. Infrequently, the heart is the primary location in affected animals and responsible for their death. Types of inflammation provoked by infectious agents that produce myocarditis include suppurative, necrotizing, hemorrhagic, lymphocytic, and eosinophilic. Suppurative myocarditis results from localization of pyogenic bacteria in the myocardium. These often originate from the vegetations of vegetative valvular endocarditis on the mitral and aortic valves. Septic infarcts with pale, disseminated lesions are present grossly in the myocardium. These foci consist of neutrophils and necrotic myocytes that form abscesses. Necrotizing myocarditis is a frequent lesion of toxoplasmosis, a common disease of cats and dogs. Hemorrhagic myocarditis occurs together with the hemorrhagic inflammation typically found in skeletal muscle of cattle with blackleg (*Clostridium chauvoei*) ([Fig. 10-67](#)). Lymphocytic myocarditis is usually a lesion of viral infections and is well illustrated by the lesions of parvoviral myocarditis of puppies ([Fig. 10-68, A and B](#)). Dogs with parvoviral myocarditis die unexpectedly and have generalized lesions of acute congestive heart failure but lack lesions in the intestine, the primary site of viral damage in approximately 95% of clinical cases. The heart is pale and flabby and has disseminated interstitial lymphocytic infiltrations and scattered myocytes with large, basophilic, intranuclear viral inclusion bodies in dogs that survive fibrosis ([Fig. 10-68, A and B](#)). East Coast fever is a tick-transmitted protozoal disease of cattle in Africa caused by *Theileria parva*, which causes myocardial necrosis and inflammation ([Fig. 10-69](#)). Eosinophilic myocarditis and the accumulation of eosinophils in the inflammatory response is the result of some parasitic infections, such as sarcocystosis. The various infectious diseases that cause myocarditis in animals are summarized in [Table 10-4](#).

591

592

**Fig. 10-67 Necrohemorrhagic myocarditis, heart, steer.** Note the area of hemorrhagic myocarditis (*arrows*) in the wall of the ventricular myocardium. **Fig. 10-68 Parvovirus myocarditis, heart, dog.** **A**, Note the multifocal pale areas (*arrow*) in the ventricular myocardium. **B**, Parvovirus infection, section of myocardium. An intranuclear basophilic inclusion body is in a myocyte (*arrow*). H&E stain. (**A**, Courtesy Dr. B. Weeks, College of Veterinary Medicine, Texas A&M University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy School of Veterinary Medicine, Purdue University.)

The pathogenesis and expected outcome of cases of myocarditis remain an important area of research because of the severity of this lesion in cardiac failure in human beings. The sequelae to myocarditis include (1) complete resolution of lesions, (2) scattered residual myocardial scars, or (3) progressive myocardial damage with acute or, in some cases, chronic cardiac failure as secondary dilated (congestive) cardiomyopathy. In experimental studies of myocarditis induced in mice by coxsackie B virus, the severity of myocarditis was influenced by the virulence of the virus and mouse strain and was enhanced by host factors such as young age, male sex, pregnancy, poor nutrition, whole-body ionizing radiation, cold environmental temperatures, alcohol ingestion, exercise, and cortisone administration. Much of the myocardial damage in coxsackie B virus infection is induced by immunologic reactions (with T lymphocyte involvement) rather than by direct viral injury.

The appearance of the heart with major myocardial diseases is illustrated in [Fig. 10-70](#).

### 10.1.2.5

#### CONDUCTION SYSTEM DISEASES

Conduction system disorders have been described mainly in dogs and horses, probably because clinical cardiologic evaluations are done most frequently in these species. Few pathologic evaluations of the tissue of the conduction system have been reported. Specific presumably inherited diseases in dogs include: (1) unexpected death in Doberman pinscher dogs associated with focal degeneration of the bundle of His; (2) syncope in pug dogs with lesions of the bundle of His; (3) intermittent sinus arrest in deaf Dalmatian dogs, presumably associated with lesions in the sinus node; (4) sinoatrial syncope (sick sinus syndrome) in female miniature schnauzers; and (5) inherited ventricular arrhythmia and sudden unexpected death in German

592

593

## Pathologic Basis of Veterinary Disease, 4th Edition

---

shepherds. Other arrhythmias in dogs and horses are atrial fibrillation and heart block. Dogs with atrial fibrillation usually have short survival times and have atrial dilation with mitral insufficiency, but some horses survive longer and at necropsy have atrial myocardial fibrosis. Heart block of the first degree (incomplete), second degree (incomplete with dropped beats), and third degree (complete) has been associated with myocardial lesions such as areas of scarring in horses and dogs. However, some investigators consider second-degree heart block in horses a normal phenomenon.

### VIRAL

Canine parvovirus, encephalomyocarditis, foot-and-mouth disease, pseudorabies, canine distemper, cytomegalovirus, Newcastle disease, avian encephalomyelitis, Eastern and Western equine encephalomyelitis

### BACTERIAL

Blackleg (*Clostridium chauvoei*), listeriosis (*Listeria monocytogenes*), Tyzzer's disease (*Bacillus piliformis*), necrobacillosis (*Fusobacterium necrophorum*), tuberculosis (*Mycobacterium* spp.), caseous lymphadenitis (*Corynebacterium pseudotuberculosis*), disseminated infections by *Actinobacillus equuli*, *Staphylococcus* sp., *Corynebacterium kutscheri*, *Pseudomonas aeruginosa*, and *Streptococcus pneumoniae*

### PROTOZOAN

Toxoplasmosis (*Toxoplasma gondii*), sarcocystosis (*Sarcocystis* sp.), neosporosis (*Neospora caninum*), encephalitozoonosis (*Encephalitozoon cuniculi*), trypanosomiasis (Chagas' disease [*Trypanosoma cruzi*])

### PARASITIC

Cysticercosis (*Cysticercus cellulosae*), trichinosis (*Trichinella* spp.)

### IDIOPATHIC

Eosinophilic myocarditis

Persistent atrial standstill (silent atria, atrioventricular myopathy) is a progressive cardiac disease of English springer spaniels and Siamese cats characterized by notable atrial dilation and fibrosis.

Atrial fibrillation occurs in cattle in association with right atrial dilation and fibrosis and alterations in the sinoatrial node. Also, sudden cardiac death is described in racehorses with right atrial myocardial fibrosis, fibrosis of the upper ventricular septum, and arteriosclerosis of intramyocardial arteries.

10.1.2.6

### NEOPLASTIC DISEASES

Various primary and secondary neoplasms develop either in or near the heart. The primary neoplasms include rhabdomyoma, rhabdomyosarcoma, schwannoma, and hemangiosarcoma. Rhabdomyomas and rhabdomyosarcomas are rare in animals and form gray nodules in the myocardium that often project into the cardiac chambers. Congenital rhabdomyomatosis in pigs and guinea pigs is really a nonneoplastic hamartoma (i.e., malformation often resembling a neoplasm that is composed of an overgrowth of mature cells and tissues that normally occur in the affected organ). Multiple, pale, poorly circumscribed areas are scattered in the myocardium and are composed of large glycogen-laden myocytes. Schwannomas involve cardiac nerves in cattle and appear as single or multiple white nodules detected as incidental findings at slaughter.

Cardiac hemangiosarcoma is an important neoplasm of dogs and can arise either in the heart (primary) or by metastasis (secondary) from sites such as the spleen. This neoplasm is usually seen in the wall of the right atrium and only occasionally involves the right ventricle. Grossly, protruding red to red-black blood-containing masses are located on the epicardial surface (Fig. 10-71) and may also protrude into the atrial lumen. Rupture produces fatal hemopericardium and cardiac tamponade. Microscopically the

## Pathologic Basis of Veterinary Disease, 4th Edition

neoplasms are composed of scattered, elongated, plump neoplastic endothelial cells, which may or may not form vascular spaces containing blood (Fig. 10-72). Pulmonary metastases are frequent.

Malignant lymphoma (lymphosarcoma) often causes lesions in the hearts of cattle, and these can be severe enough to cause death from cardiac failure. Cardiac lesions may also be present in dogs and cats with malignant lymphoma. The neoplastic cell infiltration can be diffuse or nodular and involve the myocardium and pericardium. Lymphomatous tissue appears as white masses that resemble deposits of fat (Fig. 10-73, A, and B). Microscopically, extensive infiltrations of neoplastic lymphocytes are present between myocytes (Fig. 10-74). Other generalized neoplasms, such as malignant melanomas, occasionally have metastatic lesions in the heart.

593

594

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Heart base tumors are primary neoplasms of extracardiac tissues in dogs, but they arise at the base of the heart and can produce vascular obstruction and cardiac failure. The most common neoplasm arising at this location is the aortic body tumor or chemodectoma (paraganglioma), but occasionally ectopic thyroid or parathyroid tissue gives origin to neoplasms in this area. The aortic body is a chemoreceptor organ. In some cases, aortic body tumors become large, white, firm masses that surround and compress the great vessels and atria ([Fig. 10-75](#)). Brachycephalic dog breeds are most frequently affected. Microscopically the neoplastic cells are polyhedral with vacuolated cytoplasm and are supported by an abundant, fine connective tissue stroma.

The most common cardiac diseases in the dog and cat are summarized in [Table 10-5](#). The appearance of the heart with major neoplastic diseases is illustrated in [Fig. 10-76](#).

### 10.2 VASCULAR SYSTEM

#### 10.2.1 INTRODUCTION

##### 10.2.1.1 NORMAL MORPHOLOGY

The vascular system is subdivided into arterial, capillary, venous, and lymph segments. The arteries are classified into three types: elastic arteries, muscular arteries, and arterioles. The venous vessels are termed venules and veins. The lymph vasculature includes lymph capillaries and lymph vessels. Interposed between the arterial and venous segments are the capillary beds. A vascular segment termed the microcirculation includes arterioles, capillaries, and venules and is the major area of exchange between the circulating blood and the peripheral tissue.

594

595

Fig. 10-71 **Hemangiosarcoma, heart, right atrium, dog.** A dark-red hemangiosarcoma protrudes from the wall of the right atrium (RA), a predilection site in the dog for this tumor (*arrows*). RV, Right ventricle. (Courtesy College of Veterinary Medicine, University of Illinois.)

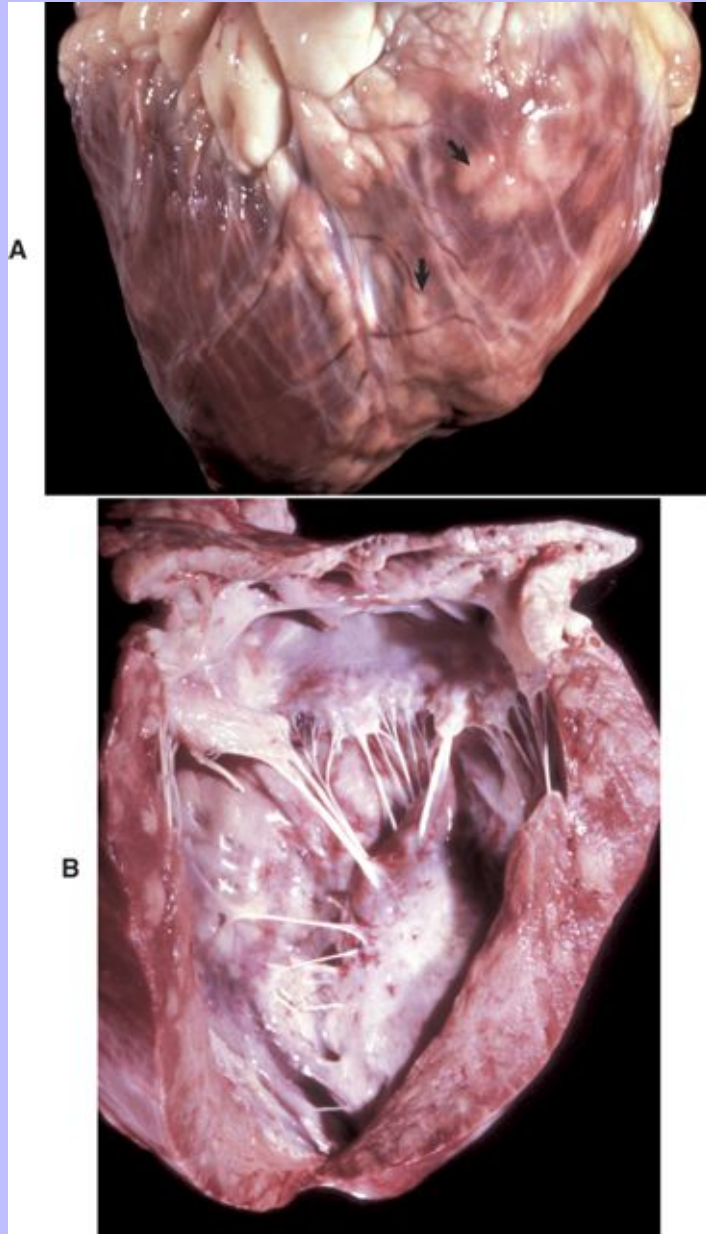

Fig. 10-72 **Hemangiosarcoma, heart, right atrium, dog.** The tumor consists of spindle cells with large, round-to-oval nuclei and numerous mitotic figures (*inset*). In this case, these cells have formed poorly delineated and haphazardly arranged vascular channels. The golden-brown pigment is hemosiderin that forms secondary to erythrophagocytosis of damaged or effete erythrocytes. H&E stain. (**Figure and inset**, courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

**Fig. 10-73 Lymphosarcoma, heart, myocardium, cow.** **A**, Sites of infiltrating neoplastic lymphocytes in the ventricular myocardium are evident as numerous white areas and nodules (*arrows*). **B**, Similar white areas of tumor are visible in the section of the left ventricular wall and subendocardially in the ventricular septum. (*A and B, Courtesy College of Veterinary Medicine, University of Illinois.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The overall design of the blood and lymph vessels is similar, except that luminal diameter, wall thickness, and the presence of other anatomic features, such as valves, vary between the different segments. The luminal surface of all vessels is lined by longitudinally aligned endothelial cells lying over a basal lamina.

595

596

Vessel walls are divided into three layers or tunics: intima, media, and adventitia. However, some of the layers can be deleted or all of the layers can be thinned in some segments of the vascular system, depending on the intravascular pressures. The large elastic arteries, such as the aorta, have (1) an intima composed of endothelium and subendothelial connective tissue, (2) a very thick tunica media composed of fenestrated elastic laminae with interposed smooth muscle cells and ground substance and bordered internally by the internal elastic lamina and externally by the external elastic lamina, and (3) an outer tunica adventitia layer composed of collagen and elastic fibers and connective tissue cells with penetrating blood vessels, termed the vasa vasorum, supplying nutrients to the adventitia and the outer half of the media. In muscular arteries and arterioles, the tunica media is composed largely of smooth muscle cells arranged in a circumferential pattern. Arterioles are the smallest arterial channels and are generally less than 100  $\mu\text{m}$  in diameter and with one to three layers of smooth muscle cells in the tunica media.

**Fig. 10-74 Lymphosarcoma, heart, section of myocardium, cow.**

Neoplastic lymphocytes have extensively infiltrated between the cardiomyocytes. Extensive infiltration can result in myocyte atrophy and loss. H&E stain. (Courtesy School of Veterinary Medicine, Purdue University.)

Fig. 10-75 **Chemodectoma (heart base tumor), aortic body, dog.** Note the large mass (arrow) at the base of the heart (H). L, Lungs. (Courtesy College of Veterinary Medicine, University of Illinois.)

Table 10-5 Most Common Cardiac Diseases in the Dog and Cat

Dog	Cat
1. Valvular endocardiosis	1. Hypertrophic cardiomyopathy
2. Congenital heart disease	2. Dilated cardiomyopathy
3. Dilated cardiomyopathy	3. Hyperthyroidism-associated hypertrophy
4. Hemorrhagic pericardial effusion	4. Congenital heart disease

Capillaries are 5 to 10  $\mu\text{m}$  in diameter, and their endothelium is one of three types: (1) continuous, (2) fenestrated (as in the endocrine glands), and (3) porous (as in renal glomeruli). The endothelium rests on an external lamina surrounded by pericytes. Pericytes are located abluminally to capillaries and postcapillary venules and because of their location, contractility, and cytoskeletal proteins may play a role in regulating capillary and venular blood flow. Lesions of the endothelium might not be evident by light microscopy, and electron microscopy is required for characterization.

Veins have thin walls in relation to their luminal size when compared with those of arteries, in which blood pressure is greater. The adventitia is the thickest layer. Valves are present to prevent retrograde blood flow (i.e., away from the heart).

Lymph capillaries lack a basal lamina. Large lymph vessels are similar in structure to veins and generally have large lumina, thin walls, and intimal valves, but contain lymph.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 10.2.1.2 REACTIONS TO INJURY

The response of vessels to injury involves a complex interaction among the cellular and noncellular elements of the vessel wall and the cellular and noncellular elements of the blood. The key cells of vessels in these reactions are endothelial cells and smooth muscle cells. Endothelial cells are metabolically active and provide a thromboresistant monolayer at the interface of blood and the vessel wall. Key functions of endothelial cells include prostacyclin production, macromolecular transport, and recruitment of inflammatory cells. Injury of endothelial cells is followed by separation from the underlying basement membrane and increased permeability to movement of plasma proteins into the subendothelium. Necrosis of endothelium will expose subendothelial collagen and elicit thrombus formation. Endothelial cells at the margin of denuded areas proliferate and reendothelialize the damaged area. The arterial intima has regional differences in the uptake of macromolecules, as well as other unique structural and functional features that result in lesion-prone areas of the vasculature. Bilirubin staining of the intima results in yellow discoloration in jaundiced animals (Fig. 10-77).

596

597

Fig. 10-76 Schematic diagram of the locations of the major cardiac neoplasms. (Redrawn with permission from School of Veterinary Medicine, Purdue University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

The other major cellular component of vessels involved in reaction to injury is the smooth muscle cell. These cells have important functions, including production of extracellular components such as collagen, elastin, and proteoglycans; maintenance of vascular tone; blood monocyte recruitment; lipoprotein metabolism; production of bioactive lipids, such as prostaglandins; and formation of oxygen-free radicals. These functions are regulated by a wide variety of biochemical mediators, such as various growth factors, cytokines, and inflammatory mediators.

10.2.1.3

### POSTMORTEM ALTERATIONS

Usually 12 to 24 hours after death, erythrocytes lyse, and the resultant imbibition of hemoglobin produces red discoloration of the normally white intima of blood vessels. Postmortem clotting must be differentiated from thrombosis. Postmortem clots, found in veins and large elastic arteries as red “currant jelly” type or occasionally as pale “chicken fat” type, are readily removed by traction or gentle flushing at necropsy, in contrast to thrombi, which are adherent. Postmortem contraction of muscular arteries because of rigor mortis extrudes blood. Microscopically, these muscular arteries are devoid of blood, and their internal elastic lamina is wavy in cross sections of the contacted vessel.

597

598

**Fig. 10-77 Jaundice, heart, aorta, dog.** Note yellow discoloration of the aortic intima. (*Courtesy School of Veterinary Medicine, Purdue University.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 10.2.2 ARTERIAL DISEASES

#### 10.2.2.1 ANEURYSMS AND RUPTURES

An aneurysm is a localized dilation or outpouching of a thinned and weakened portion of a vessel. Usually arteries are affected, especially large elastic arteries, but the lesion can also occur in veins. Known causes include copper deficiency in pigs (Fig. 10-78), as copper is necessary for normal development of elastic tissue, and damage from infection with *Spirocerca lupi* in dogs or *Strongylus vulgaris* in horses. Most cases are idiopathic. Dissecting aneurysms are infrequent but have been seen in birds (Fig. 10-79). They result from disruption of the intima, which allows entry of blood into the media, and this dissects along the wall. Aneurysms can rupture. Usually the consequences are rapidly fatal, as rather large arteries typically are involved.

Aortic rupture and rupture of large arteries can be the sequela of severe trauma or occur spontaneously. Sudden rupture of the ascending aorta in horses is associated with notable exertion and severe trauma to the ventral thorax from falling. Death ensues rapidly from cardiac tamponade, as the tear is in that portion of the aorta within the pericardial sac. In horses, the internal carotid artery can rupture into the adjacent guttural pouch, with subsequent epistaxis. This is a consequence of deep mycotic infection of the guttural pouch. Rupture of the middle uterine artery may occur during parturition in mares and with uterine torsion or prolapse in cows. Aortic rupture, with or without dissection, is an important cause of death in male turkeys.

**Fig. 10-78 Dissecting aneurysm, copper deficiency, heart, pulmonary artery, right ventricle (RV), pig.** The dark, blood-filled, bulging segment of the wall of the pulmonary artery (*arrows*) has resulted from disruption of elastic fibers. (Courtesy School of Veterinary Medicine, Purdue University.)

Fig. 10-79 **Dissecting aneurysm, aorta, turkey.** Blood has dissected through the tunica media (in a nearby section of the aorta) and in this section has come to lie in the outer layers of the tunica media and adventitia. L, Vessel lumen. H&E stain. (Courtesy School of Veterinary Medicine, Purdue University.)

598

### 10.2.2.2 GROWTH DISTURBANCES

599

Arterial hypertrophy is a response to sustained increases in pressure or volume loads. Affected vessels are generally muscular arteries, and the increase in wall thickness is predominantly because of hypertrophy (and, to some degree, hyperplasia) of smooth muscle cells of the tunica media. Muscular pulmonary arteries of cats are frequently affected, and the lesion has been associated with infection by several parasites, including *Aelurostrongylus abstrusus* (the lungworm of cats), *Toxocara* sp., and *Dirofilaria immitis* (Fig. 10-80). However, the lesions often occur in the absence of parasitic infections (Fig. 10-81). Often, no clinical disease is associated with the lesion in cats, but asthmatic signs have been seen in cats with these parasitic infections. Similar hypertrophy of muscular pulmonary arteries occurs in cattle with hypoxia-induced pulmonary arterial vasoconstriction and subsequent pulmonary hypertension associated with right side heart failure from exposure to high altitudes (so-called high-altitude disease or “brisket disease”) (see Stages of Myocardial Hypertrophy and Myocardial Diseases). Also, animals with cardiovascular anomalies that shunt blood left to right result in pulmonary hypertension and have hypertrophy of the muscular pulmonary arteries. Uterine arteries in pregnant animals also are hypertrophic.

### 10.2.2.3 DEGENERATION AND NECROSIS

Generalized vascular degenerative diseases in animals are classified into three principal groups: arteriosclerosis, atherosclerosis, and arterial medial calcification. Arteriosclerosis is characterized by intimal fibrosis of large elastic arteries, atherosclerosis is characterized by intimal and medial lipid deposits in elastic

## Pathologic Basis of Veterinary Disease, 4th Edition

and muscular arteries, and arterial medial calcification has characteristic mineralization of the walls of elastic and muscular arteries.

**Fig. 10-80 Medial hypertrophy, periarteritis, dirofilariasis, lung, small pulmonary arteries, cat.** Note the massively thickened tunica media of the small branches of the pulmonary arteries and their periarterial cuff of chronic inflammatory cells and some eosinophils. H&E stain. (Courtesy School of Veterinary Medicine, Purdue University.)

**Fig. 10-81 Medial hypertrophy, lung, small pulmonary arteries, cat.** Proliferation of smooth muscle cells (*arrows*) has resulted in marked thickening of the tunica media. Note luminal narrowing. H&E stain. (Courtesy School of Veterinary Medicine, Purdue University.)

Arteriosclerosis is an age-related disease that occurs frequently in many animal species but rarely causes clinical signs. The disease develops as chronic degenerative and proliferative responses in the arterial wall

## Pathologic Basis of Veterinary Disease, 4th Edition

and results in loss of elasticity (“hardening of the arteries”) and luminal narrowing. The abdominal aorta is most frequently affected, but other elastic arteries and peripheral large muscular vessels may be involved. Lesions are often localized around the orifices of arterial branches. Etiologic factors in the development of arteriosclerosis are not well defined, but the significant role of hemodynamic influences is suggested by the frequent involvement at arterial branching sites, where blood flow is turbulent. Grossly the lesions are seen as slightly raised, firm, white plaques. Microscopically, initially the intima is thickened by accumulation of mucopolysaccharides and later by the proliferation of smooth muscle cells in the tunica media and fibrous tissue infiltration into the intima. Splitting and fragmentation of the internal elastic lamina are common.

Atherosclerosis, the vascular disease of greatest importance in human beings, occurs only infrequently in animals and rarely leads to clinical disease, such as infarction of the heart or brain. The principal alteration is accumulation of deposits (atheroma) of lipid, fibrous tissue, and calcium in vessel walls, which eventually results in luminal narrowing. Many studies have established that the pig, rabbit, and chicken are susceptible to the experimental disease produced by the feeding of a high-cholesterol diet; the dog, cat, cow, goat, and rat are resistant. Lesions of the naturally occurring disease have been detected in aged pigs and birds and in dogs with hypothyroidism that develop an accompanying hypercholesterolemia. Arteries of the heart, mesentery, and kidneys are prominently thickened, firm, and yellow-white (Fig. 10-82). Microscopically, lipid globules accumulate in the cytoplasm of smooth muscle cells and macrophages, often termed “foam cells,” in the media and intima (Fig. 10-83). Necrosis and fibrosis develop in some arterial lesions.

599

**Fig. 10-82 Coronary atherosclerosis, hypothyroidism, heart, left ventricle, dog.** The affected coronary arteries are prominent and cordlike (*arrows*) with thickened walls. The diffuse and focal yellow areas in the walls of the arteries are the sites of atheromatous deposits. (Courtesy School of Veterinary Medicine, Purdue University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Arterial medial calcification is a frequent lesion in animals that often have concurrent endocardial mineralization and involves both elastic and muscular arteries. The causes of arterial medial calcification include calcinogenic plant toxicosis, vitamin D toxicosis, renal insufficiency, and severe debilitation, as seen in cattle with Johne's disease (Fig. 10-84). Medial calcification occurs spontaneously in rabbits and in aged guinea pigs and rats with chronic renal disease. Affected arteries, such as the aorta, have a unique gross appearance; they appear as solid, dense, pipelike structures with raised, white, solid intimal plaques (Fig. 10-85). Microscopically, in elastic arteries prominent basophilic granular mineral deposits are present on elastic fibers of the media, but in muscular arteries they form a complete ring of mineralization in the tunica media (Fig. 10-86). Siderocalcinosis (so-called iron rings), the result of deposition of both iron and calcium salts, occurs in the cerebral arteries of aged horses. Lesions in the surrounding brain tissue are generally absent. Siderocalcinosis lesions are considered incidental.

**Fig. 10-83 Atherosclerosis, meningeal artery, horse.** Note extensive accumulation of lipid-laden (clear vacuoles) “foam cells” throughout the thickened media. H&E stain. (*Courtesy School of Veterinary Medicine, Purdue University.*)

**Fig. 10-84 Johne's disease, arteriosclerosis, aorta, cow.** Multiple prominent, white, mineralized foci are in the tunica intima and media (*arrows*). (*Courtesy College of Veterinary Medicine, University of Illinois.*)

Arterial intimal calcification (intimal bodies) are distinctively small, mineralized masses within the subendothelium in small muscular arteries and arterioles of horses (Fig. 10-87). They have no deleterious effect.

Hyaline degeneration, fibrinoid necrosis, and amyloidosis are vascular lesions of small muscular arteries and arterioles and occur in all animal species. These lesions are generally not detected grossly, but in some diseases with fibrinoid necrosis of vessels, hemorrhages and edema are seen in affected organs at necropsy. The microscopic feature shared by these lesions is the formation of a homogeneous eosinophilic zone in the vessel wall. Special stains allow differentiation into three types: (1) amyloid confirmed by Congo red and methyl violet; (2) fibrinoid deposits, positive by the periodic acid–Schiff technique; and (3) negative staining of hyaline deposits by these stains. Amyloidosis and hyaline degeneration are often observed in small muscular arteries of the myocardium, lungs, and spleen of old dogs. Lesions in the intramyocardial arteries can cause small foci of myocardial infarction.

**Fig. 10-87 Intimal body (arrow), intestine, muscular artery, horse.** Intimal bodies are distinctive small, mineralized masses within the subendothelium of small muscular arteries and arterioles of horses. They are an incidental finding and have no pathologic significance. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fibrinoid necrosis of arteries is associated with endothelial damage and is characterized by entry and accumulation of serum proteins followed by fibrin polymerization in the vessel wall. These materials form an intensely eosinophilic collar that obliterates cellular detail. This lesion is frequent in many acute degenerative and inflammatory diseases of small arteries and arterioles. It is particularly frequent in pigs and is an important diagnostic feature in cases of selenium–vitamin E deficiency (heart), edema disease (gastric submucosa), cerebrospinal angiopathy, and organic mercury toxicosis (meninges). Fibrinoid necrosis is seen frequently in dogs with uremia and in dogs with hypertension, although hypertension is an uncommon finding in animals compared with human beings.

In pigs with selenium–vitamin E deficiency, the vascular fibrinoid necrosis produces gross lesions of cardiac hemorrhage (“mulberry heart disease”) (Figs. 10-88 and 10-89) and massive hemorrhagic hepatic necrosis (hepatosis dietetica) (see Fig. 8-72). With either form of the disease, fibrinoid necrosis of small muscular arteries and arterioles is widespread and is accompanied by endothelial damage and fibrin thrombi in capillaries, especially capillaries of the myocardium. (Figs. 10-90 and 10-91). This complex of vascular lesions has been termed dietary microangiopathy. Similar capillary lesions of endothelial damage and occlusion by fibrin thrombi are seen in the cerebellum of ischemia-induced encephalomalacia of vitamin E–deficient chicks and in the skin and skeletal muscles of selenium–vitamin E–deficient chicks with exudative diathesis.

601

602

**Fig. 10-88 “Mulberry heart disease,” suffusive hemorrhage, epicardium, right ventricle, heart, pig.** Red areas of suffusive hemorrhage (“mulberry-like”) are present on the epicardial surface of the right ventricle. (Courtesy Dr. M.A. Miller, College of Veterinary Medicine, University of Missouri; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Cerebrospinal angiopathy in pigs is characteristically sporadic in pigs with signs of nervous system disease. Vascular lesions, in fibrinoid necrosis, are present consistently in arteries of the central nervous system. Similar lesions occur in the arteries of the gastric submucosa of pigs with edema disease, a form of colibacillosis, and many researchers believe that cerebrospinal angiopathy represents a subacute form of edema disease ([Figs. 10-92](#) and [10-93](#)).

Medial necrosis and hemorrhage is a distinctive lesion produced in muscular arteries and arterioles of dogs and rats by a wide variety of vasoactive drugs. These vascular lesions, detected during evaluations of new compounds, produce grossly apparent hemorrhage, especially in the epicardium. Microscopically, acute damage is evident as necrosis of smooth muscle cells in the tunica media with surrounding erythrocytes. Healing lesions will have fibrosis of the vessel wall and perivascularly.

Fig. 10-89 **“Mulberry heart disease,” hemorrhage and necrosis, left and right ventricular myocardium, transverse section, pig.** Red and pale mottled areas are caused by hemorrhage and necrosis, respectively. (Courtesy Dr. M.A. Miller, College of Veterinary Medicine, University of Missouri; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

### 10.2.2.4 THROMBOSIS AND EMBOLISM

Thrombosis represents the process of intravascular coagulation during life. Predisposing factors to thrombosis include (1) endothelial damage, (2) turbulence or stasis of blood flow, and (3) hypercoagulable states. Endothelial damage can be a feature of many arterial diseases. It is frequently present in arteritis but is uncommon in most of the degenerative arterial diseases, such as fibrinoid necrosis and atherosclerosis.

602

Alterations in blood flow occur with vascular or cardiac/valvular lesions that cause turbulence; stasis of blood flow can accompany congestive cardiac failure and cardiovascular collapse, as occurs in systemic shock. Hypercoagulable states have occurred in dogs with amyloidosis and some types of renal disease.

603

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Examples of arterial thrombosis frequently observed in animals include caudal aortic thromboembolism in cats and dogs with primary cardiomyopathy (Fig. 10-94), thrombosis of mesenteric and intestinal arteries in horses with verminous arteritis from migrating larvae of strongylosis (Fig. 10-95), thrombosis of the pulmonary arteries in dogs with dirofilariasis, and aortoiliac thrombosis in horses. In these diseases, because large arteries can be affected, ischemia results in the peripheral tissue unless adequate collateral circulation exists. Recently formed mural thrombi appear as yellow, firm masses of fibrin adhered focally to the arterial intima (Fig. 10-96). Fibroblastic proliferation and organization develop within days in thrombi.

**Fig. 10-93 Fibrinoid necrosis of small arteries, edema disease, stomach, submucosa, pig.** Note the circumferential eosinophilic material in the walls of the arterioles and the extensive edema and mild hemorrhage in surrounding submucosa. H&E stain. (Courtesy School of Veterinary Medicine, Purdue University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Thrombosis or embolism of the coronary arteries can result in myocardial infarction (Fig. 10-97) and cardiac failure. These lesions are much less common in animals than in human beings. Affected animals generally have one of several types of coronary arterial disease, including atherosclerosis, arteriosclerosis, or periarteritis. In atherosclerosis associated with hypothyroidism (discussed previously), severe lesions are present in the extramural (epicardial) coronary arteries of dogs, but this only rarely leads to thrombosis and myocardial infarction. In contrast, severe arteriosclerosis of intramural cardiac arteries in aged dogs can cause small multifocal myocardial infarcts. Affected dogs often also have valvular endocardiosis, also an age-related disease.

603

604

**Fig. 10-94 Aortic thrombosis, aorta and external iliac arteries, dog.** The tan thrombus occluding the caudal abdominal aorta is a cranial extension of the red saddle thrombus at the aortic bifurcation and in the external iliac arteries (*arrows*). (Courtesy College of Veterinary Medicine, University of Illinois.)

Disseminated intravascular coagulation, initiated by a variety of causes, results in formation of widespread clotting within arterioles and blood capillaries. This clotting phenomenon is due largely to (1) endothelial damage with exposure of subendothelial collagen and subsequent platelet aggregation and (2) intravascular activation of the coagulation process. Diseases that can be accompanied by disseminated intravascular coagulation include bacterial endotoxemias; certain viral infections, such as feline infectious peritonitis and infectious canine hepatitis; dirofilariasis; certain neoplastic diseases, such as hemangiosarcoma and leukemia; shock; hemolysis; and extensive tissue necrosis, such as occurs in animals with burns. Extensive clotting depletes coagulation factors (termed consumption coagulopathy), which results in widespread hemorrhages. Hemorrhagic lesions produced by this mechanism include hemorrhagic renal cortical necrosis (Shwartzman-like reaction) or hemorrhagic adrenal gland necrosis in cases of septicemia. Microscopically, organs with disseminated intravascular coagulation have numerous fibrin thrombi in arterioles and capillaries

604

605

## Pathologic Basis of Veterinary Disease, 4th Edition

---

(Fig. 10-98). Fibrinolysis, an intravascular enzymatic process to lyse clots, can continue to be active following the death of the animal and can lead to failure to observe fibrin thrombi in autolyzed tissue.

**Fig. 10-96 Arterial thrombus, pulmonary artery, dog.** Arterial thrombi are composed primarily of platelets and fibrin because the rapid flow of blood tends to exclude erythrocytes from the thrombus, and thus arterial thrombi are usually pale beige to gray (*arrow*).

## Pathologic Basis of Veterinary Disease, 4th Edition

Embolism is the occlusion of arteries by lodgment of foreign materials, such as disrupted fragments of thrombi (thromboemboli), neoplastic cells, and bacteria. Thromboemboli originating from thrombotic lesions are either bland (sterile) or septic. Septic emboli most often originate from lesions of vegetative endocarditis. Right-sided lesions are disseminated to the lungs and left-sided lesions to the myocardium, kidneys, spleen, joints, and leptomeninges. Nonseptic emboli include air bubbles or hair fragments forced into the circulation during intravenous injections, release of fat from the bone marrow into the vasculature from fractures, release of fragments of dead intravascular parasites such as *Dirofilaria immitis* into the pulmonary circulation of carnivores following administration of adulticidal drugs (Fig. 10-99), and introduction of fragments of fibrocartilage into spinal arteries of dogs and less frequently other species (pig, human beings, horse, cat, and turkey) from disruption of degenerated intervertebral disk material (Fig. 10-100).

Animals with fibrocartilaginous embolism of the spinal vasculature develop infarction of the spinal cord, with resulting posterior paresis or paralysis. Affected dogs are typically middle-aged large or giant breeds, but occurrence in young Irish wolfhounds has been reported. The mechanism of formation of the arterial emboli is still unclear, but retrograde movement within the spinal vasculature of fibrocartilaginous fragments from degenerated intervertebral disks is generally considered to underlie the presence of these unusual emboli.

**Fig. 10-99 Verminous arteritis, dirofilariasis, pulmonary artery, dog.** A dead adult *Dirofilaria immitis* (DI) parasite in the lumen of the pulmonary artery is surrounded by pyogranulomatous inflammatory cells adhered to the wall (left) of the artery. Note the loss of the endothelial cells on the left side of the artery. H&E stain. (Courtesy School of Veterinary Medicine, Purdue University.)

Thromboembolism of the pulmonary arterial tree, often life threatening, occurs in dogs and cats. A wide variety of predisposing conditions that may result in altered blood flow, hypercoagulability, or endothelial

605

damage includes sepsis, immune-mediated hemolytic anemia, protein-losing nephropathy or enteropathy, disseminated intravascular coagulation, cardiac disease, neoplastic disease, hyperadrenocorticism, dirofilariasis, amyloidosis, and use of intravenous catheters.

**Fig. 10-100 Fibrocartilaginous emboli, spinal cord, pig.** The basophilic masses (*arrows*) occluding small arteries (cross sections) in the spinal cord gray matter adjacent to the central canal (*top left margin*) are fibrocartilaginous emboli. H&E stain. (Courtesy School of Veterinary Medicine, Purdue University.)

Thrombosis of the femoral artery, with resulting partial to complete occlusion, has been reported in cavalier King Charles spaniels. The condition may share a common etiopathogenesis with valvular endocardiosis, which is frequent in this breed, through a genetically mediated connective tissue disorder. Affected dogs generally do not develop hindlimb ischemia, in contrast to human patients with this condition, because of extensive collateral circulation.

In cattle, thrombosis of the caudal vena cava occurs in association with rupture of hepatic abscesses into either the hepatic vein or the caudal vena cava.

### 10.2.2.5

#### INFLAMMATION

The various portals of entry and defense mechanisms involved in arterial inflammation are summarized in [Box 10-1](#) and [Box 10-2](#). Arteritis occurs as a feature of many infections and immune-mediated diseases ([Table 10-6](#)). Often, all types of vessels are affected rather than only arteries, and then vasculitis or angiitis is the term applied to the lesions. In inflamed vessels, leukocytes are present within and surrounding the walls, and damage to the vessel wall is evident as fibrin deposits or necrotic endothelial and smooth muscle cells. As a result of endothelial damage, thrombosis which can result in ischemic injury or infarction in the circulatory field may be present. The “diamond skin” lesions of porcine erysipelas caused by *Erysipelothrix rhusiopathiae* is an example of cutaneous infarction ([Fig. 10-101](#)).

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 10-6 Diseases That Cause Vasculitis in Animals

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Arteritis and vasculitis can develop from endothelial injury caused by either infectious agents or immune-mediated mechanisms or may be caused by local extension of suppurative and necrotizing inflammatory processes. Equine viral arteritis is a systemic viral infection with a tropism for vascular endothelial cells. In this disease, affected small muscular arteries have lesions of fibrinoid necrosis, extensive edema, and leukocytic infiltration (Fig. 10-102). Grossly the vascular injury is reflected by severe edema of the intestinal wall and mesentery accompanied by notable accumulation of serous fluids in body cavities.

Arteritis is a prominent feature of several parasitic diseases. In canine dirofilariasis (heartworm infection), maturation of adult parasites occurs in the pulmonary arteries and right atrium and ventricle. The pulmonary arteries containing parasites initially have an infiltration of the intima (termed endarteritis) by eosinophils, with subsequent development of an irregular fibromuscular proliferation of the intima visible grossly as a rough granular or shaggy appearance of the luminal surface (Fig. 10-99). Live or dead parasites can be present within these vascular lesions and be accompanied by thromboembolism and pulmonary infarction.

606

607

Infection of horses by *Strongylus vulgaris* is now less common because of widespread use of highly efficacious antiparasitic drugs. During its larval development, the parasite migrates through the intestinal arteries, and the most severe lesions are generally found in the cranial mesenteric artery. The affected vessel is enlarged, and its wall is firm and fibrotic. The intimal surface often has an adhering thrombus admixed with larvae. Microscopically the affected vessel has extensive infiltration of inflammatory cells and proliferation of fibroblasts throughout the wall. As a consequence, thromboembolism of the intestinal arteries frequently occurs and can produce colic, but the abundant collateral circulation to the equine intestinal tract makes intestinal infarction an unusual event.

**Fig. 10-102 Acute arteritis, equine viral arteritis, small intestine, submucosa, horse.** Small arteries have fibrinoid degeneration (circumferential eosinophilic material) of the tunica media with leukocytic infiltration. The surrounding loose connective tissue is edematous and also infiltrated by numerous leukocytes. H&E stain. (Courtesy School of Veterinary Medicine, Purdue University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Polyarteritis is a disease that occurs sporadically in many animal species and is an important disease of aged rats (Fig. 10-103). Many recent reports have described the occurrence of polyarteritis in a disease termed idiopathic necrotizing polyarteritis involving the coronary and meningeal arteries in pet and laboratory beagle dogs (“beagle pain syndrome”). Clinically, affected dogs typically show recurrent episodes of fever, body weight loss, and occasionally cervical pain manifested by a still gait and stiff neck with a hunched body posture. However, some affected dogs will not display clinical signs of disease. The lesions are usually attributed to an immune-mediated vascular injury. Medium-sized muscular arteries in a wide variety of organs, including the heart and meninges, are selectively involved and grossly appear thick and tortuous, have associated focal hemorrhage, and develop aneurysms and thrombosis. Microscopically the early lesions include fibrinoid necrosis and leukocytic invasion of the intima and media (Fig. 10-104). In chronic lesions, inflammatory cells and fibrosis involve all layers of the vascular wall.

**Fig. 10-103 Polyarteritis nodosa, mesenteric arteries, rat.** The affected segments of the arteries are thick, red, hemorrhagic and tortuous (arrows). (Courtesy School of Veterinary Medicine, Purdue University.)

### 10.2.2.6 NEOPLASTIC DISEASES

Neoplasms arising from vascular endothelial cells develop in many different organs. Hemangiomas are benign neoplasms often found in the skin of dogs (Fig. 10-105). These red, blood-filled masses are well circumscribed. The malignant neoplasm hemangiosarcoma occurs frequently in the spleen and the right atrium of dogs. This neoplasm is also generally a red mass, but microscopically the neoplastic cells are pleomorphic and may not form distinct vascular spaces. Another neoplasm of vascular origin is the hemangiopericytoma of the canine skin. The distinctive microscopic feature is a laminated arrangement of elongated, plump neoplastic pericytes around small blood vessels.

607

608

## Pathologic Basis of Veterinary Disease, 4th Edition

Metastasis of primary sarcomas to distant sites often occurs after invasion of blood vessels. The major arterial diseases are illustrated in [Fig. 10-106](#).

### 10.2.3 VENOUS DISEASES

#### 10.2.3.1 CONGENITAL ANOMALIES

Portocaval shunts occur in dogs and, because blood bypasses the liver, can result in signs of nervous system disease associated with failure of hepatic degradation of nitrogenous products such as ammonia (resulting in hyperammonemia). The resulting nervous system syndrome is termed hepatic encephalopathy. Specifically the shunts represent retained fetal vascular structures, as in persistent ductus venosus, or arise from prominent dilation of various portosystemic shunts that normally are quite small vessels. See [Chapter 8](#) on diseases of the liver for further details.

#### 10.2.3.2 DILATION

A venous dilation from weakened vascular walls is termed a varicosity (localized involvement) or phlebectasia (generalized alteration). Although a frequent lesion in the superficial veins of the legs in women, it is rather uncommon in animals. The pampiniform plexus in the spermatic cord in aged rams and bulls can be affected.

Fig. 10-106 Schematic diagram of the major arterial diseases. (Redrawn with permission from School of Veterinary Medicine, Purdue University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 10.2.3.3 INFLAMMATION

The various portals of entry and defense mechanisms involved in venous inflammation are summarized in [Box 10-1](#) and [Box 10-2](#). Phlebitis is a common vascular lesion and is often complicated by thrombosis. The vascular lesion arises from (1) systemic infections, (2) local extension of infection, and (3) a faulty intravenous injection procedure. Systemic infections with phlebitis as a lesion include salmonellosis in several species and feline infectious peritonitis. In pigs with various septicemias, such as salmonellosis and colibacillosis, the gastric fundic mucosa is often severely congested and hemorrhagic because of venous endothelial damage and thrombosis. In severe local infections, such as in metritis or hepatic abscesses, inflammation extends into the walls of adjacent veins and produce phlebitis, with or without thrombosis. Intravenous injections of irritant solutions, injecting solutions into the vascular wall, or intimal trauma produced by indwelling venous catheters result in vascular damage and create an opportunity for localization and proliferation of infectious agents and development of phlebitis and thrombosis ([Fig. 10-107](#)). Animals with phlebitis complicated by thrombosis have the additional risk of septic embolism, which can cause endocarditis and pulmonary abscesses.

608

609

**Fig. 10-107 Thrombus (mural), jugular vein (opened), dog.** Note the nodular mural thrombus (*left*) in the jugular vein. This thrombus likely occurred at a site of venipuncture and a subsequent phlebitis. The smooth-surfaced reddish-tan thrombus (*right*) extending toward the heart is a trailing thrombus, connected to the mural thrombus. (*Courtesy School of Veterinary Medicine, Purdue University.*)

Omphalophlebitis (“navel ill”) is inflammation of the umbilical vein and often occurs in neonatal farm animals because of bacterial contamination of the umbilicus immediately following parturition. Bacteria from this site can cause septicemia, suppurative polyarthritis, hepatic abscesses (the umbilical vein drains into the liver), and umbilical abscesses.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Cats with feline infectious peritonitis often develop phlebitis in various abdominal organs. This lesion appears to result from deposition of immune complexes, which subsequently induce an inflammatory reaction in affected vessels. Occasionally, in some cattle with hepatic abscesses, infection extends into the adjacent large hepatic veins and results in formation of a septic thrombus in the caudal vena cava. Rupture and release of the contents of the abscess into the lumen can cause multiple septic emboli in the pulmonary capillaries and unexpected death of the affected animal.

Several parasitic diseases important in tropical regions of the world are characterized by presence of parasites in the lumens of veins. These diseases include schistosomiasis (blood fluke infection—*Schistosoma* spp.) and infection of cats in South America by *Gurltia paralyans*. Affected cats have spinal cord damage from thrombophlebitis in the lumbar veins, associated with the presence of adult parasites in affected vessels. In schistosomiasis, adult parasites are present in the mesenteric and portal veins, and the resulting phlebitis is characterized by intimal proliferation and thrombosis.

### 10.2.4 LYMPH VESSEL DISEASES

#### 10.2.4.1 CONGENITAL ANOMALIES

Hereditary lymphedema has been described in dogs, Ayrshire calves, and pigs. Affected animals have prominent subcutaneous edema that, in calves, often causes severe swelling of the tips of the ears. Interference with lymph drainage results from defective development of the lymph vessels that are aplastic or hypoplastic.

#### 10.2.4.2 DILATION AND RUPTURE

Lymphangiectasis is dilation of lymph vessels. The cause may be a congenital anomaly ([Fig. 10-108](#)) or due to obstruction of lymph drainage by invading masses of malignant neoplasms ([Fig. 10-109](#)). Another example is intestinal lymphangiectasis, an important disease of dogs in which there is a protein-losing enteropathy. Lacteals in the intestinal villi are prominently dilated, and lymph vessels throughout the wall of the bowel and the mesentery are distended. The role of obstruction of lymph vessels in the pathogenesis of this disease is still unclear. Many diseases with severe acute inflammatory alterations accompanied by vascular damage, as with the pneumonia of bovine pasteurellosis, have prominently dilated lymph vessels.

Fig. 10-108 **Congenital lymphangiectasia, epicardium, young horse.** Note the tortuous appearance of the epicardial lymphatic vessel (*arrow*). In congenital lymphangiectasia, lymph vessels fail to make connections with other vessels or are obstructed because of anomalous development. (*Courtesy College of Veterinary Medicine, University of Illinois.*)

609

Fig. 10-109 **Acquired lymphangiectasia, lymphoma (lymphosarcoma), mesentery, horse.** Note the distended lymphatics on the serosal surface of the large colon, the result of impeded lymph flow through the mesenteric lymph nodes at the root of the mesentery, due to obstruction of flow in the lymph node secondary to compression of the lymphatic cortical and medullary lymph sinuses by neoplastic lymphocytes. (Courtesy College of Veterinary Medicine, University of Illinois.)

Table 10-7 Diseases That Cause Lymphangitis in Animals

### MYCOTIC

Epizootic lymphangitis of horses (*Histoplasma farciminosum*), sporotrichosis (*Sporothrix schenckii*)

### PARASITIC

*Brugia* spp. infection of dogs and cats

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Rupture of the thoracic duct, either as a result of trauma or from spontaneous disruption, causes chylothorax in dogs and cats (see [Fig. 9-90](#)). However, many cases of chylothorax occur without injury to the thoracic duct and have been attributed to lesions that interfere with central venous return or produce obstruction of the thoracic duct (right side heart failure, neoplasms, granulomas, cranial vena cava thrombosis, dirofilariasis) or that are idiopathic.

**Fig. 10-110 Lymphangitis, forelimb, lymphatic vessels, horse.** Note the multiple swellings (cordlike) of the afferent lymphatics in the skin. These lymphatics lie in the subcutis and empty into the caudal superficial cervical (prescapular) lymph node. (*Courtesy School of Veterinary Medicine, Purdue University.*)

**Fig. 10-111 Granulomatous lymphangitis, Johne's disease, mesenteric lymph vessel, sheep.** The lymphatic is occluded by a fibrinous thrombus secondary to the destruction of the endothelium by inflammatory cells including macrophages. Early proliferating fibrous tissue and extensive edema (*E*) surround the lymph vessel. The adjacent artery and vein are unaffected. H&E stain. (Courtesy School of Veterinary Medicine, Purdue University.)

611

### 10.2.4.3 INFLAMMATION

The various portals of entry and defense mechanisms involved in lymph vessel inflammation are summarized in [Box 10-1](#) and [Box 10-2](#). Lymphangitis is a feature of many diseases ([Table 10-7](#)). The affected vessels are often located in the distal limbs and are thick, cordlike structures ([Fig. 10-110](#)). Lymphedema also can be present. Nodular suppurative lesions of lymphangitis often ulcerate and discharge pus onto the surface of the skin. In Johne's disease, the mesenteric lymph vessels are often prominent because of granulomatous lymphangitis, an extension of the enteric infection producing a granulomatous enteritis and lymphangitis ([Fig. 10-111](#)).

### 10.2.4.4 NEOPLASTIC DISEASES

Lymphangioma represents a rare benign neoplasm composed of lymph channels. Lymphangiosarcoma occurs more often than the benign neoplasm. Vascular spaces contain lymph rather than the blood. Lymph vessels are frequently invaded by primary carcinomas and are a common route of metastasis.

## 11 Chapter 11 Urinary System

SHELLEY J. NEWMAN

ANTHONY W. CONFER

ROGER J. PANCIERA

### 11.1 INTRODUCTION

#### 11.1.1 KIDNEY

Mammalian kidneys are paired organs present in the retroperitoneum, ventrolateral and adjacent to the lumbar vertebral bodies and their corresponding transverse processes. These complex organs, which function in excretion, metabolism, secretion, and regulation, are susceptible to disease insults that affect the four major anatomic structures of the kidney: the glomeruli, tubules, interstitium, and vasculature. Because of the limited ways that renal tissue can respond to injury, the patterns of injury and outcomes that initially may be distinctive in severe and prolonged diseases will result in a similar end point—chronic renal disease and failure. Interdependence between components of the nephron also are responsible for producing a narrow range of repeatable injury patterns, which students can come to recognize on gross or histologic assessment.

#### 11.1.1.1 STRUCTURE AND FUNCTION

##### 11.1.1.1.1 Macroscopic Structure

Kidneys are organized functionally and anatomically into lobules. Each lobule represents collections of nephrons separated by the medullary rays ([Fig. 11-1](#)). Renal lobules should not be confused with renal lobes. Each lobe is represented by a renal pyramid ([Fig. 11-1](#)). Among domestic animals, carnivores and horses have unilobar (or unipyramidal) kidneys. Porcine and bovine kidneys are multilobar (or multipyramidal), but only bovine kidneys have external lobation ([Fig. 11-2](#)). Kidneys are covered by a diffuse fibrous capsule that in normal kidneys can be easily removed from the renal surface. The renal parenchyma is divided into a cortex and medulla ([Fig. 11-3](#)). The corticomedullary ratio is usually approximately 1:2 or 1:3 in domestic animals. The ratio varies among species; for example, those adapted to the desert have a far larger medulla and thus a corticomedullary ratio that can approach 1:5. Normally the cortex is radially striated and dark red-brown except in mature cats, in which the cortex is often yellow because of the large lipid content of tubular epithelial cells. The renal medulla is pale gray and has either a single renal papilla, as in cats; a fused, crestlike papilla (renal medullary crest), as in dogs, sheep, and horses; or multiple renal papillae, as in pigs and cattle. The medulla generally can be subdivided into an outer zone, that portion of the medulla close to the cortex, and an inner zone, that portion closer to the pelvis. Papillae are surrounded by minor calyces that coalesce to form major calyces, which empty into the renal pelvis, where urine collects before entry into the ureters.

Knowledge of the normal renal blood supply is important in understanding the pathogenesis and distribution of various renal lesions. The kidneys receive blood primarily through the renal artery. An interlobar artery extends along the boundary of each renal lobe (renal column) and then branches at right angles to form an arcuate artery that runs along the corticomedullary junction ([Fig. 11-4](#)). Interlobular

613

614

## Pathologic Basis of Veterinary Disease, 4th Edition

arteries branch from the arcuate artery and extend into the cortex. They have no anastomoses, making them susceptible to focal ischemic necrosis (infarct) as in any organ with end arteries.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

11.1.1.1.2

### Microscopic Structure

The functional unit of the kidney is the nephron, which includes the renal corpuscle (glomerulus within Bowman's capsule), and a tubular system that includes the proximal convoluted tubules, the loop of Henle, and the distal convoluted tubule, which empties into the collecting tubule (Fig. 11-5).

The glomerulus is a complex, convoluted tuft of fenestrated endothelial-lined capillaries held together by a supporting structure of cells in a glycoprotein matrix, the mesangium (Fig. 11-6). The capillary tuft is covered by the visceral epithelial cells (podocytes) and is contained within a membranous "cap," called Bowman's capsule, which is lined by parietal epithelial cells (resembling squamous epithelium) (Fig. 11-6). The fluid that filters through the glomerulus into the capsular space (also referred to as Bowman's space) is called glomerular filtrate and it arises after passage through the glomerular filtration membrane (composed of fenestrated endothelial cells, basement membrane, and filtration slits located between visceral epithelial cells or podocytes). This ultrafiltrate of plasma (primary urine), which contains water, salts, ions, glucose, and albumin, passes into the capsular space (Bowman's space) and then empties into the proximal convoluted tubule at the urinary pole.

The glomerular filtration barrier is composed of podocytes, fenestrated endothelium, and basal lamina, the last produced by both endothelial and epithelial cells (Fig. 11-7). The glomerular basement membrane has a thick, dense central layer, the lamina densa, which is covered by thinner, more electron-lucent inner and outer layers, the lamina rara interna and lamina rara externa, respectively. The basement membrane has a network of type IV collagen, which forms a tetrameric porous infrastructure. Numerous glycoproteins, such as acidic proteoglycans and laminin, together with the collagen fibers form the complete structure of the membrane. Visceral epithelial cells (podocytes), aligned on the external surface of the basement membrane, are responsible for synthesis of basement membrane components and have special cytoplasmic processes (foot processes) that are embedded in the lamina rara externa. Negatively charged glycoproteins overlying the endothelial cells and the podocytes contribute to the charge differential of the glomerular basement membrane. Foot processes from adjacent visceral epithelium interdigitate to form filtration slits between them. Filtration slit diaphragms are composed of nephrin, a cell adhesion molecule of the immunoglobulin superfamily, which controls slit size by its connection to podocyte actin (Fig. 11-7). The glomerular filtration barrier selectively filters molecules based on size (<70,000 Da), electrical charge (the more cationic, the more permeable), and capillary pressure. In summary, both size-dependent and charge-dependent filtration is possible because of the porous structure of capillary walls, which is a function of endothelial fenestrations, a basement membrane formed of type IV collagen, basement membrane anionic glycoproteins, and filtration slits of the visceral epithelium. The entire glomerular tuft is supported by mesangial matrix that is secreted by the mesangial cells, a type of modified pericyte (Fig. 11-8). Mesangial cells are pluripotent mesenchymal cells that are contractile and phagocytic, which besides being capable of synthesizing collagen and mesangial matrix, also secrete inflammatory mediators.

Fig. 11-8 Schematic diagram of the functions and organization of the mesangium. (From Kierszenbaum AL: Histology and cell biology: an introduction to pathology, St Louis, 2002, Mosby.)

In addition to the principal glomerular function of plasma filtration, glomerular functions also include regulation of blood pressure by means of secreting vasopressor agents and/or hormones, regulation of peritubular blood flow, regulation of tubular metabolism, and removal of macromolecules from circulation by the glomerular mesangium. Integral to these functions is the juxtaglomerular apparatus, which functions in tubuloglomerular feedback by autoregulating renal blood flow and glomerular filtration rate. The juxtaglomerular apparatus is composed of four components: (1) an afferent arteriole whose smooth muscle is modified to form myoepithelial cells, which are the juxtaglomerular cells that secrete renin; (2) an efferent arteriole; (3) the macula densa; and (4) the extraglomerular mesangium (Fig. 11-9). Renin, produced by cells of the juxtaglomerular apparatus, stimulates the production of angiotensin I from circulating angiotensinogen. The angiotensin-converting enzyme in the macula densa converts angiotensin I to angiotensin II, which then functions to constrict afferent renal arterioles; maintain renal blood pressure; stimulate aldosterone secretion from the adrenal gland, thus increasing sodium reabsorption; and stimulate antidiuretic hormone (ADH) release. ADH principally increases the permeability of collecting tubules to water and increases the permeability of the medullary region to urea.

The proximal and distal convoluted tubules are linked by the loop of Henle, which is divided into a descending and an ascending limb. The wall of the descending limb and initial portion of the ascending limb is thin (permeable), whereas the cortical portion of the ascending limb is thick (impermeable) (Fig. 11-5). The uriniferous tubule is the name given to the nephron and the collecting duct.

The proximal tubule is lined by columnar epithelial cells that have a microvillous (brush) border, which greatly increases their absorptive surface. A major function of the proximal tubules is to reabsorb sodium, chloride, potassium, albumin, glucose, water, and bicarbonate. This is facilitated by luminal brush border, basolateral infoldings, magnesium-dependent sodium and potassium pumps, and transport proteins. The

## Pathologic Basis of Veterinary Disease, 4th Edition

proximal tubule is continuous with the loop of Henle that is in close physiologic and anatomic association with the peritubular capillary network (within the cortex) and the vasa recta (within the medulla). The loop of Henle, via a countercurrent mechanism and sodium and potassium ATPase pumps, absorbs  $\text{Na}^+$  and  $\text{Cl}^-$  ions, producing a hypotonic filtrate that flows into the next portion of the nephron—the distal convoluted tubule. Here, water is reabsorbed from the tubule into the interstitium because of a solute concentration gradient and by the effects of antidiuretic hormone. The filtrate is further concentrated in the collecting ducts by water and sodium reabsorption by a sodium-potassium ATPase pump and additional water reabsorption into the medullary interstitium by a urea gradient. Intercalated cells of the collecting tubule regulate acid-base balance and reabsorb potassium. Thus the final excretory product, urine, is formed (Fig. 11-10).

Fig. 11-9 Schematic diagram of the counter-current multiplier and exchanger. (From Kierszenbaum AL: Histology and cell biology: an introduction to pathology, St Louis, 2002, Mosby.)

## Pathologic Basis of Veterinary Disease, 4th Edition

The interstitium consists of a relatively scant connective tissue stroma, primarily present as a reticular meshwork found around and between uriniferous tubules. Blood vessels, nerves, and lymphatics are also present in the renal interstitium.

**Fig. 11-10 Schematic diagram of the renin-angiotensin-aldosterone system.**  
(From Kierszenbaum AL: Histology and cell biology: an introduction to pathology, St Louis, 2002, Mosby.)

Interlobular arteries have small branches that become afferent glomerular arterioles, which enter the renal corpuscle and subsequently exit at the vascular pole as efferent glomerular arterioles (Fig. 11-4). Efferent arterioles supply the blood for the extensive network of capillaries that surround the cortical and medullary tubular system of the kidneys, known as the peritubular capillary network. The latter surrounds cortical segments of the tubules and then drains into the interlobular vein, arcuate vein, interlobar vein, and ultimately the renal vein. Additionally, the vasa recta are formed from the deeper portions of the

621

622

## Pathologic Basis of Veterinary Disease, 4th Edition

---

peritubular network and descend into the medulla and around the lower portions of the loops of Henle before ascending to the cortex and emptying into venous vessels that connect to the interlobular and arcuate veins. The vasa recta parallel the descending and ascending limbs of the loop of Henle and the collecting ducts (Fig. 11-5).

11.1.1.1.3

### Renal Function

Renal function can be summarized into five basic components:

1. Formation of urine for the purpose of elimination of metabolic wastes.
2. Acid-base regulation, predominantly through reclamation of bicarbonate from the glomerular filtrate.
3. The conservation of water through reabsorption by the proximal convoluted tubules, the countercurrent mechanism of the loop of Henle, antidiuretic hormone activity in the distal tubules, and the urea gradient in the medulla. The tubular system is capable of absorbing up to 99% of the water in the glomerular filtrate.
4. The maintenance of normal extracellular potassium ion concentration through passive reabsorption in the proximal tubules and tubular secretion in the distal tubules under the influence of aldosterone.
5. Endocrine function through three hormonal axes: renin-angiotensin (Fig. 11-9), most importantly, but also erythropoietin and vitamin D. Erythropoietin, produced in the kidneys in response to reduced oxygen tension, is released into the blood and stimulates bone marrow to produce erythrocytes. Vitamin D is converted in the kidneys to its most active form (1,25-dihydroxycholecalciferol [calcitriol]), which facilitates calcium absorption by the intestine.

11.1.1.2

### PORTALS OF ENTRY

The renal system can be exposed to injurious stimuli and agents (e.g., bacteria by various routes, including ascension from the exterior via the urethra, urinary bladder, and ureters hematogenously and by exposure to preformed or locally metabolized substances that are excreted through the renal tubular system (Box 11-1). The first of these is relatively unique in that few body systems have an opening to the exterior, and these are rarely blind-ended as in the urinary system. Hence, ascending infection from the exterior can localize and be perpetuated in the kidneys. Common etiologic agents in this process, such as bacteria, may originate from the exterior skin surface and the adjacent orifices of the intestinal tract or the genital tract. As in all visceral organs, the sustaining blood supply can provide a portal of hematogenous entry for infectious organisms, which in the case of the kidney leads to arterial or glomerular localization. Substances secreted into the filtrate, such as crystalline salts, can produce localized trauma to tubular lining cells. Additionally, filtered toxins or metabolized substances processed by the tubular lining epithelium exert their effect principally on the proximal tubular epithelium.

### 11.1.1.2.1 Box 11-1 Portals of Entry to the Kidney

#### 11.1.1.2.1.1 ASCENSION

- Extension from lower urinary tract secondary to gastrointestinal content contamination (diarrhea) (females primarily)
- Extension from lower urinary tract secondary to genital tract contamination (pyometra) (females exclusively)
- Extension from lower urinary tract secondary to dermal contamination (perivulvar dermatitis)

#### 11.1.1.2.1.2 HEMATOGENOUS

- Localization within corticomedullary vessels
- Septic—embolic nephritis
- Nonseptic necrosis with infarction
- Localization within large renal vasculature
- Massive infarction
- Localization within glomerular tufts
- Localization within interstitial vessels

#### 11.1.1.2.1.3 METABOLIC PROCESSING IN RENAL TUBULES

- Activation of products in proximal tubules—necrosis
- Presence of heavy metal—mercury, cadmium
- Crystalline oversaturation
- Direct toxic action—cisplatin

### 11.1.1.3 DEFENSE MECHANISMS

Defense mechanisms unique to the renal system have evolved to counteract the typical forms of injury ([Box 11-2](#)). The most notable of these includes barrier systems, such as those of the tubular basement membranes and more importantly the glomerular filtration membranes ([Fig. 11-8](#)). The latter is structurally adept at separating substances based on size and charge. Additionally, the glomerulus is equipped with its own clearance mechanism, a function of mesangial cells ([Fig. 11-9](#)). Finally, innate humoral and cellular responses by the immune system contribute to protection, but can also be responsible for renal damage.

622

11.1.1.3.1

  - Innate responses
  - Humoral responses
  - Cellular responses

11.1.1.4

**RESPONSES TO INJURY**

The response of the urinary system to injury is the response of each of its components—kidneys, ureters, urinary bladder, and urethra—to injury. This will be described sequentially in this chapter and is summarized in [Box 11-3](#). It is important to remember that the functional unit of the kidney is the nephron and that damage to any component of the nephron (renal corpuscle and tubules) results in diminished function and progressive damage to the kidney. Renal disease can be best summarized by dividing it into general tissue responses that affect the primary anatomic components: glomeruli, tubules, interstitium, and vasculature. In the early stages of diseases, specific anatomic components may be targeted by specific insults: glomeruli in immune-mediated disease and tubules in toxin-induced necrosis. But in the more chronic stages of disease, the kidney undergoes changes related to nephron loss that are not specific to the original cause but are considered common end-stage responses to many injurious stimuli.

Primary glomerular damage often occurs as a result of deposition of immune complexes, entrapment of thromboemboli and bacterial emboli, or direct viral or bacterial infection of glomerular components. Such insults are reflected morphologically by necrosis, proliferation of glomerular cells or membranes, or infiltration of leukocytes, and functionally by reduced vascular perfusion or increased vascular permeability, the latter of which is characterized by leakage of large quantities of plasma proteins and other molecules (bicarbonate ions and chloride) into the glomerular filtrate. Continued or severe injury can result in chronic changes characterized at first by atrophy and fibrosis of the glomerular tuft and secondarily by atrophy of renal tubules. Similar chronic glomerular changes can result from reduced blood flow or chronic loss of tubular function.

	Thrombosis
	Sclerosis
	Basement membrane thickening
	Endothelial cell hypertrophy

Renal tubular epithelial cells can respond to injury by undergoing degeneration, necrosis, apoptosis, and/or atrophy. The basement membrane can respond by rupture or thickening. Tubular disease occurs as a result of tubular epithelial damage from the following:

## Pathologic Basis of Veterinary Disease, 4th Edition

---

1. Blood-borne infections (innocent bystander effect)
2. Ascending infections (intratubular pathogens)
3. Direct damage from toxins (intratubular effects)
4. Ischemia

When nephrons are lost because of injury, remaining tubules can undergo compensatory hypertrophy in an attempt to maintain overall renal function, but there is no regeneration of nephrons. In many instances of tubular epithelial cell necrosis, particularly as a response to toxins, tubular epithelium can regenerate and contribute to restoration of function. Severe damage to or loss of tubular basement membranes, as occurs following ischemic damage, results in necrosis and loss of tubular segments, failure of functional repair, and permanent loss of function of the entire nephron. Tubular atrophy can occur secondary to the following:

623

624

1. External compression
2. Interstitial fibrosis
3. Intratubular obstruction
4. Diminished glomerular perfusion and filtration
5. Reduced oxygen tension

The renal interstitium is the fibrovascular stroma that surrounds the nephron and is significantly involved in renal diseases, whether or not this is of primary interstitial origin or subsequent to tubular damage, it is often referred to as tubulointerstitial disease. Interstitial inflammation occurs as the result of ascending urinary tract infections (pyelonephritis), systemically derived infections of tubules and interstitium, and secondary to injury of tubules or glomeruli. Common acute lesions of the interstitium include edema, hemorrhage, and inflammation characterized by infiltration of neutrophils. As lesions become subacute to chronic, neutrophils become less prominent, and in several diseases, infiltrates of macrophages, lymphocytes, and plasma cells predominate. With chronic injury to or following atrophy of nephrons, fibrosis of the interstitium can be severe, resulting in notable reduction in nephron function and perpetuation of the renal disease.

Injury to or obstruction of any component that significantly decreases or blocks renal function can result in major systemic effects, including azotemia; uremia; plasma protein loss; water, electrolyte, and acid-base imbalances; retention of drugs; and hyperparathyroidism and osteodystrophy of renal origin.

### 11.1.2 LOWER URINARY TRACT

#### 11.1.2.1 STRUCTURE AND FUNCTION

The lower urinary tract is the conduit for the transport of urinary waste from the kidney to the exterior through paired ureters, the urinary bladder, and the urethra. The ureters enter the bladder wall obliquely and are covered by a mucosal flap, the vesicoureteral valve, which is an important structure because it normally prevents reflux of urine from the bladder into the ureter and renal pelvis. At death, the urinary bladder can contract to such a degree that the normal bladder wall appears thick on necropsy. The normal mucosa of the lower urinary tract should be smooth and glistening. Urine should be clear except in horses, where it is

## Pathologic Basis of Veterinary Disease, 4th Edition

cloudy because of the normal presence of mucus and crystalline material produced by the branched tubuloalveolar mucous glands in the submucosa of the renal pelvis and proximal ureter.

The renal pelvis, ureters, and urinary bladder are lined by transitional epithelium, whereas the urethra is lined by transitional epithelium cranially and stratified squamous epithelium immediately cranial to or at the urethral orifice. Histologically the ureteral mucosa is folded longitudinally; there are poorly defined internal and external longitudinal muscle layers, a prominent middle circular muscle layer, and externally either adventitia or peritoneal serosa. As in other mucous membranes, the lamina propria has small lymphoid follicles which, following inflammation or antigenic stimulation, can be large enough to be seen grossly as discrete, circular, white foci (1 to 2 mm) in the mucosa. The function of the ureter is to propel urine from the kidney to the bladder by peristalsis. Histologically the bladder is an expanded ureter, lined by pseudostratified transitional epithelium ranging from 3 to 14 cells thick, depending on the species and degree of distention. The urinary bladder stores urine, and in concert with the urethra, expels it. During continence, the bladder is relatively flaccid and the urethra acts as a valve. During micturition, contraction of the detrusor muscle (the urinary bladder musculature) pumps urine through the relaxed urethra.

11.1.2.2

### PORTALS OF ENTRY

The lower urinary system can be exposed to injurious stimuli by various routes including the following:

1. Ascension from the external urinary and genital orifices
2. Exposure to preformed, variably concentrated toxins excreted in the urine
3. Following hematogenous spread of infectious organisms, principally bacteria and viruses (Box 11-4)

Damage secondary to ascension of injurious stimuli is a distinct mechanism because the lower urinary tract represents a tubular system that is blind-ended and has only one exit to the exterior, unlike the intestinal system, which is a continuous tubular system. This predisposes to bacterial ascension and entrapment, especially in females. In males, end-stage obstruction is due to the narrow diameter and length of the urethra. Etiologic agents, such as bacteria, may originate from the exterior skin surface or the closely located openings of the intestinal tract and the female genital tract. Bacteria with adhesion capabilities may overcome peristalsis and periodic urine flushing. Regular complete emptying will minimize risks of pathologic changes, in contrast to stasis, retention of urine, and infrequent urinations, which predispose to ascending disease. Concentration of excreted urinary substances can damage the surface of the lower urinary system and predispose it to infection, secondary hyperplasia, or neoplastic responses. The importance of blood supply cannot be overlooked as a portal of entry to the lower urinary tract. The vasculature provides sustenance to the lower urinary system, but compression of thin-walled veins predisposes the urinary bladder to hypoxia and spread of organisms, such as bacteria and viruses.

### DEFENSE MECHANISMS

Defense mechanisms unique to the lower urinary system have evolved to counteract the typical forms of injury ([Box 11-5](#)). The most notable of these are as follows:

1. The flushing action of urine
2. Peristalsis
3. Inhospitable environment for bacterial growth controlled by urine pH
4. Protective urothelial mucus coating
5. Innate humoral immune response
6. Cellular immune responses

### 11.2 DISEASES OF THE KIDNEY

#### 11.2.1 DEVELOPMENTAL ABNORMALITIES

##### 11.2.1.1 RENAL APLASIA, HYPOPLASIA, AND DYSPLASIA

Renal aplasia (agenesis) is the failure of development of one or both kidneys, such that there is no recognizable renal tissue present. In these cases, the ureter may be present or absent. If present, the cranial extremity of the ureter begins as a blind pouch. A familial tendency for renal aplasia has been observed in Doberman pinscher and beagle dogs. Because life can be sustained when more than one fourth of renal function is maintained, unilateral aplasia is compatible with life, provided that the other kidney is normal. Unilateral aplasia can go unnoticed during life and be recognized at necropsy. Bilateral aplasia is obviously incompatible with life and occurs sporadically.

Renal hypoplasia designates incomplete development of the kidneys, such that fewer than normal nephrons are present at birth. Renal hypoplasia has been documented as an inherited disease of purebred or crossbred Large White pigs in New Zealand and described in foals of various breeds, as well as in dogs (Fig. 11-11, A) and cats (Fig. 11-11, B). Hypoplasia can be unilateral (Fig. 11-11, B) or bilateral; it is rare, and it is difficult to diagnose subtle cases at necropsy or microscopically. In cattle and pigs, the number of renal papillae in the hypoplastic kidney can be compared with those in a normal kidney. Hypoplastic kidneys from pigs and foals have a notable reduction in the number of glomeruli. In foals, for example, 5 to 12 glomeruli are present per low-power field in affected kidneys compared with 30 to 35 glomeruli per low-power field in normal adult kidneys. Unless significant renal mass is compromised by this condition, hypoplasia is clinically silent.

Occasionally, some bovine kidneys are found to have reduced numbers of external lobes, but these kidneys are not hypoplastic and are microscopically and functionally normal; the reduction in external lobes merely represents fusion of the lobes. The shrunken, pitted kidneys in young animals, particularly dogs, are often diagnosed as hypoplastic. However, in most of these cases, these small kidneys are due to the following:

1. Renal fibrosis, resulting from renal disease developing at an early age
2. Dysplasia
3. Progressive juvenile nephropathy

Renal dysplasia is an abnormality of altered structural organization resulting from abnormal differentiation and the presence of structures not normally present in nephrogenesis. Cystic renal dysplasia has been described in sheep and is inherited as an autosomal dominant trait. Renal dysplasia occurs infrequently and, like renal hypoplasia, must be differentiated from renal fibrosis and progressive juvenile nephropathy.

Dysplastic changes can be unilateral or bilateral and can involve much of an affected kidney or occur only as focal lesions. Dysplastic kidneys can be small, misshapen, or both. Microscopically, five primary features of dysplasia are described as follows:

1. Asynchronous differentiation of nephrons inappropriate for the age of the animal—aggregates of small hypercellular glomeruli in the cortex
2. Persistence of primitive mesenchyme such that the interstitial connective tissue has a myxomatous appearance

625

627

3. Persistence of metanephric ducts
4. Atypical (adenomatoid) tubular epithelium
5. The presence of cartilaginous and/or osseous tissue

Fig. 11-11 Types of congenital developmental anomalies, kidney. **A**, Unilateral hypoplastic kidney, dorsal sections, young dog. Grossly, the affected right kidney is nearly identical structurally to the left kidney but smaller in size (hypoplasia). **B**, Unilateral hypoplastic kidney, young cat. The left kidney (ventral-dorsal view) is normal in shape and structure but reduced in overall size. **C**, Juvenile progressive nephropathy, young dog. Bilateral abnormally shaped firm kidneys. **D**, Juvenile progressive nephropathy, dorsal sections, dog. Section of the kidneys from Fig 11-11, **C**. **E**, Juvenile progressive nephropathy, chronic, dog. Note the interstitial fibrosis, tubular atrophy, dilated urinary space, and mineralization. H&E stain. **F**, Polycystic disease, dorsal section, cat. Numerous variably sized tubular cysts are present in the cortex and medulla and affect approximately 60% of the kidney. The cysts contain clear colorless fluid. This condition is hereditary, and Persian cats are predisposed. (**A**, Courtesy Dr. B. Weeks, College of Veterinary Medicine, Texas A&M University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. M. Miller, College of Veterinary Medicine, University of Missouri; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **C** and **D**, Courtesy College of Veterinary Medicine, University of Illinois. **E**, Courtesy Dr. S.J. Newman, College of Veterinary Medicine, University of Tennessee. **F**, Courtesy Dr. A. Confer, College of Veterinary Medicine, Oklahoma State University.)

Interstitial fibrosis, renal cysts, and a few enlarged hypercellular glomeruli (compensatory hypertrophy) are changes seen secondarily to the primary dysplastic changes. The number of nephrons, lobules, and calyces are normal. Bilateral renal dysplasia characterized by persistent mesenchyme and atypical tubular development has been described in foals.

Progressive juvenile nephropathy (familial renal disease) of Lhaso apso, Shih Tzu, golden retriever dogs, and perhaps other canine breeds could be examples of renal dysplasia (Fig. 11-11, C, D, and E). Asynchronous differentiation is often seen and to a lesser extent several other features of dysplasia. However, until these hereditary lesions of dogs are better characterized, it is probably best to retain the diagnostic term of progressive juvenile nephropathy.

### 11.2.1.2 ECTOPIC AND FUSED KIDNEYS

Ectopic kidneys are misplaced from their normal sublumbar location because of abnormal migration during fetal development. Ectopic kidneys occur most frequently in pigs and dogs and usually involve only one kidney. Ectopic locations often include the pelvic cavity or inguinal position. Although ectopic kidneys are

## Pathologic Basis of Veterinary Disease, 4th Edition

---

usually structurally and functionally normal, malposition of the ureters predisposes them to obstruction, which results in secondary hydronephrosis.

Fused (horseshoe) kidneys result from the fusion of the left and right cranial or left and right caudal poles of the kidneys during nephrogenesis. This fusion results in the appearance of one large kidney with two ureters. The histologic structure and function of the fused kidneys are usually normal.

11.2.1.3

### RENAL CYSTS

Renal cysts are spherical, thin-walled, variably sized distentions principally of the cortical or medullary renal tubules and are filled with clear, watery fluid. Congenital renal cysts can occur as a primary entity or in cases of renal dysplasia. The pathogenesis of primary renal cysts is not entirely understood. Cysts are likely derived from normal or noncystic segments of the nephron, most commonly the renal tubules, the collecting ducts, and Bowman's (uriniferous) space. Although genetic mechanisms can be involved in the pathogenesis of renal cysts, experiments with toxic chemicals indicate that genetic predisposition is not a requirement. Four mechanisms of renal cyst formation are considered plausible:

1. Obstruction of nephrons can cause increased luminal pressure and secondary dilation.
2. Modifications in extracellular matrix and cell-matrix interactions result in weakened tubular basement membranes allowing saccular dilation of tubules.
3. Focal tubular epithelial hyperplasia with production of new basement membranes, increased tubular secretion, and increased intratubular pressure causes development of enlarged, dilated tubules.
4. Dedifferentiation of tubular epithelial cells results in loss of polarity of cells with abnormal cell arrangements in tubules, reduced tubular fluid absorption, increased intratubular pressure, and dilation of tubules.

These mechanisms are not mutually exclusive, and several mechanisms often work in concert to create renal cysts.

Cysts range in size from barely visible to several centimeters in diameter. Cysts are usually spherical, delineated by a thin fibrous connective tissue wall lined by flattened epithelium, and are filled with clear watery fluid. The sources of fluid are glomerular filtrate, transepithelial secretions, or both. When viewed from the renal surface, the cyst wall is pale gray, smooth, and translucent. Cysts can arise anywhere along the nephron and be located in either cortex or medulla. Kidneys can have single or multiple cysts. Some cysts cause no alteration in renal function and therefore are considered incidental findings. Such incidental renal cysts are common in pigs and calves and must be differentiated from hydronephrosis. Acquired renal cysts can occur as a result of renal interstitial fibrosis or other renal diseases that cause intratubular obstruction. These cysts are usually small (1 to 2 mm in diameter) and occur primarily in the cortex.

Polycystic kidneys have many cysts that involve numerous nephrons. Congenital polycystic kidneys occur sporadically in many species, but can be inherited as an autosomal dominant lesion in pigs and lambs and can be inherited along with cystic biliary disease in Cairn and West Highland white terriers. The lesion, termed polycystic kidney disease (PKD), is inherited as an autosomal dominant trait in families of Persian cats and bull terriers. Although less well characterized in animals than in human beings, this autosomal dominant, high penetrance, heritable condition is thought to be related to mutations in one or more genes (PKD-1 and/or PKD-2) and altered function of the related proteins, principally polycystin-1 and

627

628

## Pathologic Basis of Veterinary Disease, 4th Edition

---

polycystin-2. Manifestation of tubular cysts occurs following mutation of both alleles of these genes, the first of which is a germ-line mutation, and the second of which, is somatic. Polycystin-1 is a cell membrane-associated protein with a large extracellular domain. Polycystin-1, the product of PKD-1, is involved in normal cell proliferation and apoptosis pathways. Although the exact mechanisms for cyst formation are not known, polycystin-1 mutations allow cells either to enter a differentiation pathway that results in tubule formation or to become susceptible to apoptosis. Additionally, polycystin 1 is known to be important in both cell adhesion and cell signaling because it is an essential component of desmosomes. Loss of polycystin-1 from its basolateral location may alter critical pathways controlling normal tubulogenesis, thus contributing to cyst formation. Similarly, polycystin-2 functions principally as a localized plasma membrane calcium channel. Further study of these mutated proteins will allow us to narrow the mechanistic pathway of the inherited form, and potentially extrapolate to the acquired and sporadic congenital cystic lesions documented. A polycystic renal disease with cysts arising from glomeruli has been described in collie puppies. The gross appearance of the cut surface of a polycystic kidney has been described as a “Swiss cheese” (Fig. 11-11, F). As cysts enlarge, they compress the adjacent parenchyma. When extensive regions of renal parenchyma are polycystic, renal function can be impaired.

11.2.1.4

### INHERITED ABNORMALITIES IN RENAL TUBULAR FUNCTION

Inherited abnormalities in tubular metabolism, in transport, or in reabsorption of glucose, amino acids, ions, and proteins have been described in dogs. Primary renal glucosuria, an inherited disorder in Norwegian elkhounds and of sporadic occurrence in other dog breeds, occurs when the capacity of tubular epithelial cells to reabsorb glucose is significantly reduced. Gross and histologic lesions are not expected, as this is a functional disorder. Glucosuria most commonly results from diabetes mellitus, acromegaly, or catecholamine release and predisposes dogs to the following:

1. Bacterial infections of the lower urinary tract
2. Urinary bladder emphysema, secondary to splitting of glucose molecules by bacteria (principally *Escherichia coli*, *Clostridium perfringens*, and rarely with *Candida* yeasts), with release of CO<sub>2</sub> into the bladder lumen and absorption of gas into bladder lymphatics (Fig. 11-12)

A hereditary generalized defect in tubular reabsorption similar to the Fanconi syndrome in human beings has been described in basenji dogs. The underlying tubular defect appears to be abnormal membrane structure of the proximal tubular epithelial cell brush borders because of altered lipid content in the cell membrane. Gross lesions are not identifiable in the early stages. Histopathologic changes in the kidneys are initially minimal, consisting of irregularly sized tubular epithelial cells in the convoluted tubules and loops of Henle. With time, dogs with Fanconi syndrome develop progressive renal insufficiency and associated renal fibrosis. Aminoaciduria, glucosuria, proteinuria, increased phosphaturia, metabolic acidosis, and multiple endocrine abnormalities characterize this disease clinically.

**Fig. 11-12 Emphysema, urinary bladder mucosa, cow.** The multiple “nodules” are mucosal gas bubbles that expand the mucosa and are secondary to bacterial infections of the lower urinary tract (principally by *Escherichia coli*, *Clostridium perfringens*, and rarely *Candida* yeasts), which result in splitting of glucose molecules to release CO<sub>2</sub> into the bladder lumen, from where the gas can be absorbed into bladder lymphatics. This animal was injected with calcium borogluconate as a calcium source to treat milk fever. Following intravenous injection, calcium ions readily dissociate from the parent molecule, and the resulting gluconate provides a sugar source for resident urinary bacteria. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

The excretion of large quantities of cystine in the urine (cystinuria) is a sex-linked inherited disease seen occasionally in purebred and mongrel male dogs. It is of importance because it predisposes affected dogs to calculus formation and obstruction of the lower urinary tract (see Urolithiasis).

### 11.2.2 GLOMERULAR DISEASES

All functions of the glomerulus include the following:

1. Plasma ultrafiltration
2. Blood pressure regulation
3. Peritubular blood flow regulation
4. Tubular metabolism regulation

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 5. Circulating macromolecule removal

These are affected by processes that target this structure in disease. Damage to the glomerular filtration barrier can result from several causes and produce a variety of clinical signs. The major clinical finding of glomerular disease is the leakage of various low molecular weight (small molecule size) proteins, such as albumin, into the glomerular filtrate. As a result, large quantities of albumin overload the protein reabsorption capabilities of the proximal convoluted tubular epithelium to such an extent that protein-rich glomerular filtrate accumulates in the variably dilated tubular lumina and protein subsequently appears in the urine. In such diseases, the proximal tubular cells often have microscopic eosinophilic intracytoplasmic bodies referred to as hyaline droplets, which represent accumulations of intracytoplasmic protein absorbed from the filtrate. 628  
629

Renal diseases that result in proteinuria are called protein-losing nephropathies. Protein-losing nephropathy is one of several causes of severe hypoproteinemia in animals. Prolonged, severe renal protein loss results in hypoproteinemia, reduced plasma colloid osmotic (oncotic) pressure, and loss of antithrombin III. The nephrotic syndrome is further characterized by generalized edema, ascites, pleural effusion, and hypercholesterolemia.

The pathophysiologic mechanisms of glomerular injury from infectious or chemical insults have been summarized by three theories:

1. Intact nephron hypothesis
2. Hyperfiltration hypothesis
3. The theory of complex deposition

The intact nephron hypothesis proposes that damage to any portion of the nephron affects the entire nephron function. This is seen when glomerular damage interferes with peritubular blood flow and results in decreased tubular resorption or secretion. Not all nephron damage is irreversible, but nephrons are not capable of regeneration and thus outcomes vary from hypertrophy to repair.

Unlike the intact nephron hypothesis, the hyperfiltration hypothesis helps explain the progressive nature of glomerular disease. Glomerular hyperfiltration is a result of increased hydrostatic pressure that damages delicate glomerular capillaries and in cases of prolonged hypertension produces a sustained repeating deleterious effect on the glomerulus, ultimately resulting in glomerulosclerosis. Increased dietary protein can produce a transient increase in glomerular hyperfiltration and if persistent can result in glomerulosclerosis. There may be a species effect, as dogs that undergo experimental hyperfiltration are much less prone to development of progressive glomerular disease than are rats.

The theory of complex deposition is derived from the fact that glomeruli are the primary site for removal of macromolecules (principally immune complex) from the circulation. Complexes may be deposited in subepithelial, subendothelial, or mesangial locations. These immune complexes are capable of triggering a sequence of inflammatory events including the following:

1. Recruitment and localization of inflammatory cells at the site
2. Release of inflammatory mediators and enzymes
3. Destruction of glomerular structures

## Pathologic Basis of Veterinary Disease, 4th Edition

---

4. Further compromise of nephron function
5. Continuing damage by altered transglomerular hyperfiltration and perfusion shifts between nephron populations

Different forms of glomerulonephritis including bacterial, viral, chemical, and immune-mediated will be discussed in the next section.

### 11.2.2.1 SUPPURATIVE GLOMERULITIS (EMBOLIC NEPHRITIS)

Suppurative glomerulitis, which can also be referred to as acute embolic nephritis, is the result of a bacteremia, in which bacteria lodge in random glomeruli and to a lesser extent in interstitial capillaries, and cause the formation of multiple foci of inflammation (microabscesses) throughout the renal cortex (Fig. 11-13). A specific example of embolic nephritis is actinobacillosis of foals caused by *Actinobacillus equuli*. These foals usually die within a few days of birth and have small abscesses in many visceral organs, especially the renal cortex. Embolic nephritis also occurs commonly in the bacteremias of pigs infected with *Erysipelothrix rhusiopathiae* or sheep and goats infected with *Corynebacterium pseudotuberculosis*.

Grossly, multifocal random, raised, tan pinpoint foci are seen subcapsularly and on the cut surface throughout the renal cortex. Microscopically, glomerular capillaries contain numerous bacterial colonies intermixed with necrotic debris and extensive infiltrates of neutrophils that often obliterate the glomerulus. Glomerular or interstitial hemorrhage can occur as well. As with many other inflammatory diseases, if the affected animal survives, the neutrophilic infiltrates will either persist as focal residual abscesses or be progressively replaced by increasing numbers of lymphocytes, plasma cells, and macrophages; reactive fibroblasts; and ultimately coalescing scars.

### 11.2.2.2 VIRAL GLOMERULITIS

Glomerulitis, caused by a direct viral insult to the glomerulus, occurs in acute systemic viral diseases, such as acute infectious canine hepatitis, equine arteritis virus infection, hog cholera, avian Newcastle disease, and neonatal porcine cytomegalovirus infection. The lesions are mild, usually transient, and result from viral replication in capillary endothelium. Acute viral glomerulonephritis produces the following gross lesions:

1. Kidneys are often slightly swollen.
2. Renal capsular surface is smooth.
3. Kidneys are normal color or pale.
4. Glomeruli are visible as pinpoint red dots on the cut surface of the cortex.

629

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Viral-induced intranuclear inclusions are present in glomerular capillary endothelium from viremias of infectious canine hepatitis and cytomegalovirus infections. The inclusions of each disease are similar and are usually large, basophilic to magenta, and either fill the nucleus or are separated from the nuclear membrane by a clear halo. In the other diseases (equine arteritis, hog cholera, and avian Newcastle), viral antigens can be demonstrated in endothelium, epithelium, or mesangial cells by immunofluorescence or immunohistochemistry. In cases of viral glomerulitis, lesions include endothelial hypertrophy, a thickened and edematous mesangium, hemorrhages, necrosis of endothelium, and a thickened and edematous mesangium. Clinically, animals are systemically ill from the viral infection, but the glomerular signs are specifically those of a transient proteinuria.

11.2.2.3

### CHEMICAL GLOMERULONEPHRITIS

Although much less common than the immune-mediated forms of glomerulonephritis, chemically induced glomerular disease occurs in a variety of different ways. Chemicals typically induce glomerular injury by any of the following:

1. Direct injury to glomerular epithelial cells
2. Direct injury to endothelial cells of the glomerulus
3. Altered renal blood flow
4. Induction of immunologic reactions and inflammatory responses, which may occur following:
  - a. Incorporation of drugs into immune complexes
  - b. The formation and targeted deposition of antigen-antibody complexes
  - c. The formation of antinuclear antibodies
  - d. The formation of antibasement membrane antibodies within the glomerular tuft

Puromycin aminonucleoside, adriamycin, and histamine-receptor antagonists all induce proteinuria through targeted damage to glomerular epithelial cells. The immunosuppressive drug, cyclosporine A, alters renal perfusion and ultimately the glomerular filtration rate by damaging glomerular endothelial cells. Examples of foreign substances capable of producing immune complexes include injectable hyperimmune serum, gold, and d-penicillamine. Procainamide and hydralazine result in production of antinuclear antibodies, and occupational exposure to hydrocarbon solvents can create antibasement membrane antibodies. Often drug-induced lesions lead to irreversible nephron loss and compensatory cellular and functional hypertrophy of other nephrons. The continuing physical loss of nephrons sets up a cycle for an increase in glomerular hypertension and hyperfiltration, which results in glomerulosclerosis, progressive nephron loss, and interstitial fibrosis.

630

631

11.2.2.4

### IMMUNE-MEDIATED GLOMERULONEPHRITIS

Glomerulonephritis most often results from immune-mediated mechanisms, most notably following the deposition of soluble immune complexes within the glomeruli and less commonly following the formation of antibodies directed against antigens within the glomerular basement membrane. Antibodies to the basement

## Pathologic Basis of Veterinary Disease, 4th Edition

membrane (antibasement membrane disease) bind and damage the glomerulus through fixation of complement and resulting leukocyte infiltration. This mechanism of glomerulonephritis has been well documented in human beings and nonhuman primates but only rarely in other domestic animals. To confirm the diagnosis of antibasement membrane disease, immunoglobulin (Ig) and complement (C3) must be demonstrated within glomeruli. Antibodies must be eluted from the kidneys and found to bind to normal glomerular basement membranes of the appropriate species.

Immune-complex glomerulonephritis occurs in association with persistent infections, or other diseases that characteristically have a prolonged antigenemia that enhances the formation of soluble immune complexes. In domestic animals, immune-complex glomerulonephritis occurs most commonly in dogs and cats. Immune-complex glomerulonephritis is associated with specific viral infections, such as feline leukemia virus or feline infectious peritonitis virus; chronic bacterial infections, such as pyometra or pyoderma; chronic parasitism, such as dirofilariasis; autoimmune diseases, such as canine systemic lupus erythematosus; and neoplasia (Box 11-6). In addition to the role of persistent infections, a familial tendency for development of immune-complex glomerulonephritis has been described in a group of related Bernese mountain dogs.

Immune-complex glomerulonephritis is initiated by the formation of soluble immune complexes (antigen-antibody complexes) in the presence of antigen-antibody equivalency or slight antigen excess, which then do the following:

1. Selectively deposit in the glomerular capillaries
2. Stimulate complement fixation with formation of C3a, C5a, and C567, which are chemotactic for neutrophils
3. Damage the basement membrane through neutrophil release of proteinases, arachidonic acid metabolites (such as thromboxane), and oxidants, particularly oxygen-derived free radicals and hydrogen peroxide

631

4. Continue to damage the glomeruli by the release of biologically active molecules from monocyte infiltrations in the later stages of inflammation (Fig. 11-14, A)

Although circulating immune complexes may contribute to this process, antibody binding to endogenous glomerular antigens or entrapped nonspecific antigens is more common. Direct action of C5b-C9 on the glomerular components results in activation of both glomerular epithelial cells and mesangial cells to produce damaging mediators, such as oxidants and proteases.

Many specific factors determine the extent of deposition of soluble immune complexes in the glomerular capillary walls. These include persistence of appropriate quantities of immune complexes in the circulation, glomerular permeability, the size and molecular charge of the soluble complexes, and the strength of the bond between the antigen and antibody (avidity). Small or intermediate complexes are the most damaging, because large complexes are removed from circulation through phagocytosis by cells of the monocyte-macrophage system in the liver and spleen. An increase in local glomerular vascular permeability is necessary for immune complexes to leave the microcirculation and deposit in the glomerulus. This process is usually facilitated via vasoactive amine release from mast cells, basophils, or platelets ([Fig. 11-14, A](#)). Mast cells or basophils release vasoactive amines as a result of the interaction of the immune complexes with antigen-specific IgE on the surface of these cells, by stimulation of the mast cells or basophils by cationic proteins released from neutrophils, or by the anaphylatoxin activity of C3a and C5a. Platelet-activating factor (PAF) is released from immune complex-stimulated mast cells, basophils, or macrophages and causes platelets to release vasoactive amines.

**Fig. 11-14 Schematic diagram of the mediators of immune glomerular injury and epithelial cell injury.** **A**, Mediators of immune glomerular injury. **B**, Epithelial cell injury. The postulated sequence is a consequence of antibodies to epithelial cell antigens, with subsequent toxins, cytokines, or other factors causing injury and detachment of epithelial cells, resulting in protein leakage through the defective glomerular basement membrane and filtration slits. (**A** and **B**, From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

Localization of the complexes within the various levels of the basement membrane or in subepithelial locations depends on their molecular charge and avidity. Once small, soluble immune complexes are

632

633

## Pathologic Basis of Veterinary Disease, 4th Edition

deposited within the capillary wall, they can become greatly enlarged as a result of interactions of immune complexes with free antibodies, free antigens, complement components, or other immune complexes.

After immune-complex deposition, glomerular injury can also occur from the aggregation of platelets and activation of Hageman factor, which results in the formation of fibrin thrombi that produce glomerular ischemia. Furthermore, glomerular epithelial cell and extracellular matrix damage can result directly from the terminal membrane attack complex of the activated complement cascade (C5 to C9). This can result in epithelial detachment (causing proteinuria) and, glomerular basement membrane thickening subsequent to up-regulation of epithelial cell receptors for transforming growth factor (Fig. 11-14, B). Cell-mediated cytotoxic responses (from sensitized T lymphocytes) to glomerular antigens or complexes may exacerbate renal lesions. Complexes themselves may modulate the immune response through interaction with receptors on various cells (Box 11-7).

### 11.2.2.4.2

#### Box 11-7 Progression of Glomerular Immune-Complex Deposition

Deposition affected by:

1. Appropriate quantities of immune complexes in the circulation
2. Glomerular permeability
3. The size and molecular charge of the soluble complexes
4. Strength of the bond between antigen and antibody

Glomerular permeability affected by:

1. Release of vasoactive amines from mast cells, basophils or platelets
  - a. Immune complexes interact with antigen-specific immunoglobulin E on surface of mast cells or basophils
  - b. Cationic proteins from neutrophils stimulate release of vasoactive amines from mast cells and basophils
  - c. C3a and C5a cause release of vasoactive amines
  - d. Platelets release vasoactive amines following release of platelet-activating factor from immune-complex stimulated mast cells, basophils, and macrophages

Glomerular progression affected by:

1. Aggregation of platelets, activation of Hageman factor, fibrin thrombi formation, and glomerular ischemia
2. Terminal membrane active complex of activated complement cascade damages glomerular epithelial cells and extracellular matrix resulting in epithelial cell detachment and basement membrane thickening
3. Cell mediated cytotoxic responses from T lymphocytes sensitized to glomerular antigens or complexes may exacerbate renal lesions

## Pathologic Basis of Veterinary Disease, 4th Edition

Finally, if exposure of the glomerulus to immune complexes is short lived, as in a transient infection, such as infectious canine hepatitis, glomerular immune complexes will be phagocytosed by macrophages or mesangial cells and removed, and the glomerular lesions and clinical signs may resolve. Conversely, continual exposure of glomeruli to soluble immune complexes such as in persistent viral infections (e.g., feline leukemia virus infection) and chronic heartworm disease (Fig. 11-15) can produce progressive glomerular injury, with severe lesions and clinical manifestation of glomerular disease.

Ultrastructurally, immune complexes either in the glomerular basement membrane or in a subepithelial location appear as electron-dense bodies (Figs. 11-15 and 11-16). Complexes that are poorly soluble, fairly large, or of high avidity often enter the mesangium, where they can be phagocytosed by macrophages and appear ultrastructurally as dense granular deposits within the mesangial stroma or within macrophages. Other ultrastructural changes commonly seen are loss or effacement of visceral epithelial cell foot processes, cytoplasmic vacuolation, retraction and detachment of visceral epithelium, and infiltrates of neutrophils and monocytes within the mesangium.

635

**Fig. 11-15 Immune-complex glomerulonephritis, kidney, glomerulus, dog.** Transmission electron photomicrograph of a glomerulus with immune-complex deposits due to dirofilariasis. A heartworm microfilaria is present in the capillary lumen (*arrowheads*). The basement membrane is irregularly thickened and contains granular, electron-dense deposits (*arrows*). The podocytic foot processes are fused. TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. N. Cheville, College of Veterinary Medicine, Iowa State University.)

**Fig. 11-16 Schematic diagrams of the antibody-mediated glomerular injury.** Antibody-mediated glomerular injury can result either from the deposition of circulating immune complexes (**A**) or from formation of complexes in situ (**B** and **C**). Antiglomerular basement membrane (*anti-GBM*) disease (**B**) or antitubular deposits (**C**) are characterized by linear immunofluorescence patterns, whereas lesions caused by immune complexes reveal granular patterns. **D** and **E**, Two patterns of deposition of immune complexes as seen by immunofluorescence microscopy: granular, characteristic of circulating and in situ immune complex nephritis (**D**); and linear, characteristic of classic anti-GBM disease (**E**). (*A through E, From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

A diagnosis of immune-mediated glomerulonephritis can be made by immunofluorescent or immunohistochemical demonstration of immunoglobulin and complement components, usually C3, in glomerular tufts. In dogs, IgG or IgM are the most common isotypes demonstrated in glomerulonephritis; however, combinations of IgG, IgM, and IgA also occur in the glomeruli of some dogs. In one study, IgA was the only immunoglobulin found in three dogs with immune-complex glomerulonephritis. Both Ig and C3 are usually demonstrated in a granular (“lumpy-bumpy”) pattern using immunofluorescent or immunohistochemical techniques (Fig. 11-17); however, in antibasement membrane disease, as reported in human beings and horses, the antibody deposits have a linear distribution conforming to the basement membranes (Fig. 11-16). It is important to remember that fluorescing deposits indicate the presence of immunoglobulin or complement but do not specifically indicate the presence of disease. Additionally, immunofluorescence may be negative when all reactive binding sites are occupied, thus complicating diagnosis of this condition.

The diagnosis of preformed immune-complex glomerulonephritis can be confirmed only by demonstrating that the antibodies from the immune complexes, eluted from glomeruli, are not capable of binding to normal glomerular elements and hence represent deposition of preformed circulating complexes. Once this has been done, the ideal situation would be to identify the causative antigen present in the immune complexes. This process is accomplished by eluting antibodies from diseased glomeruli and attempting to identify their specificity for suspected antigens. For example, antibodies eluted from the glomeruli of dogs with glomerulonephritis associated with severe heartworm disease bind to several *Dirofilaria immitis* antigens, including the body wall of adult worms, parasitic uterine fluid, and microfilaria. In most cases of immune-complex glomerulonephritis, the specific causative antigen usually escapes determination. Demonstration of electron-dense deposits in mesangial, subepithelial, or subendothelial locations by electron microscopy is also supportive of the diagnosis of immune-mediated glomerulonephritis.

**Fig. 11-17 Immune-complex glomerulonephritis, kidney, glomerulus, mink.** Intraglomerular immunoglobulin deposits demonstrated by immunofluorescence. Newman, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Gross lesions of acute immune-complex glomerulonephritis are usually subtle. The kidneys are often slightly swollen, have a smooth capsular surface, are of normal color or pale, and have glomeruli that are visible as pinpoint red dots on the cut surface of the cortex (Fig. 11-18). The normal glomeruli of horses are usually visible, so this feature of pinpoint red dots for glomeruli cannot be used for diagnosis in that species. If lesions do not resolve but become subacute to chronic, the renal cortex becomes somewhat shrunken and the capsular surface has a generalized fine granularity. On cut surface, the cortex can be thinned and granular, and glomeruli can appear as pinpoint pale gray dots. With time, more severe scarring can develop throughout the cortex (see Renal Fibrosis).

Microscopically, immune-complex glomerulonephritis has several histopathologic forms. Although various classifications of glomerulonephritis have been published, the following simple classification is well understood among veterinary pathologists. Lesions in glomeruli may be described as proliferative, membranous, or membranoproliferative (Figs. 11-19 and 11-20). Glomerular lesions can be distributed diffusely, when most of the glomeruli are involved; focally, when only a certain proportion of glomeruli are involved; globally, when an entire glomerular tuft is involved; and segmentally, when only a portion of the glomerular tuft is affected. Most of the lesions in immune-complex glomerulonephritis are diffuse, but within an individual affected glomerulus, the lesions can be either global or segmental.

635

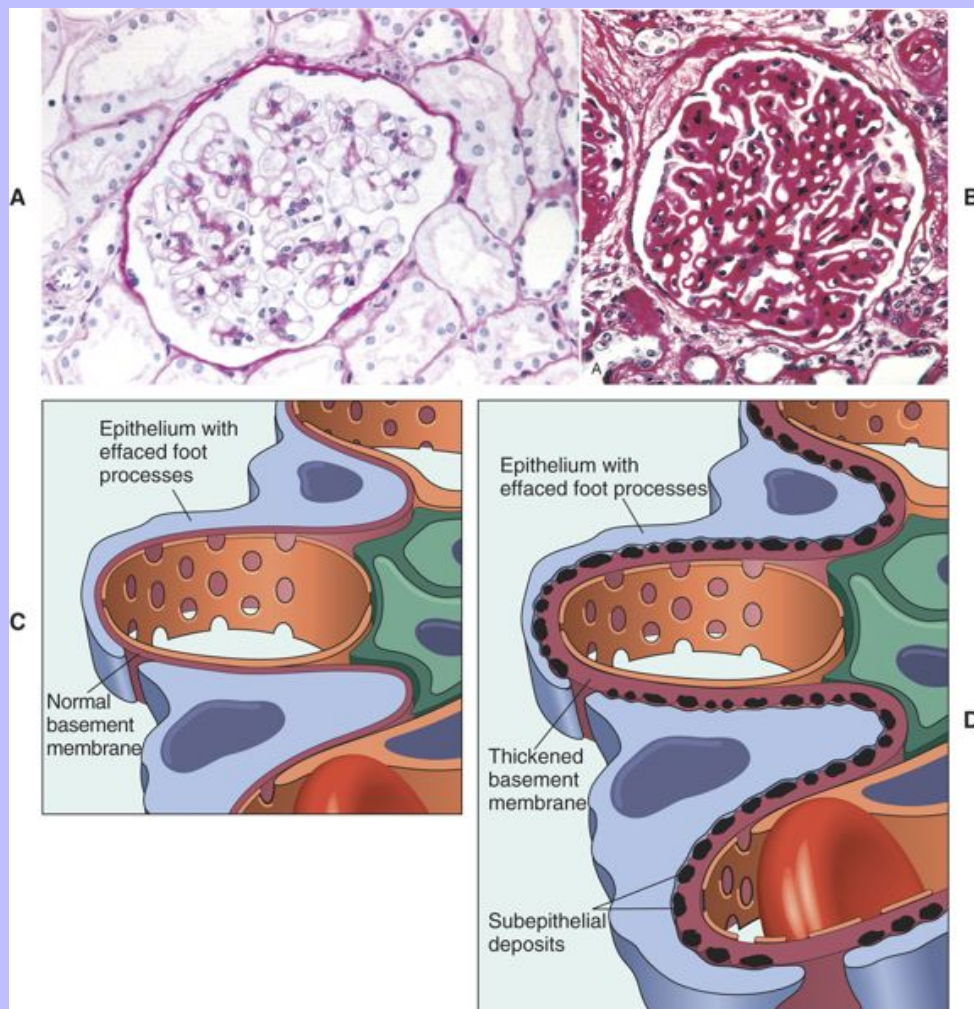

636

**Fig. 11-18 Proliferative glomerulonephritis, kidney, dorsal section, dog.**

PAS reaction. **B**, Membranous glomerulonephritis. The glomerular basement membrane is diffusely thickened. PAS reaction. **C**, Lupoid nephrosis. Diffuse loss of foot processes of visceral epithelial cells. **D**, Membranous glomerulonephritis is characterized by subepithelial deposits, which by transmission electron microscopy are electron dense, and by loss of foot processes. (*A through D*, From Cotran RS, Rennke H, Kumar V: The kidney and its collecting system, ed 7, Philadelphia, 2002, Saunders.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Microscopic details of each type of glomerular disease are outlined in the next section.

11.2.2.4.3

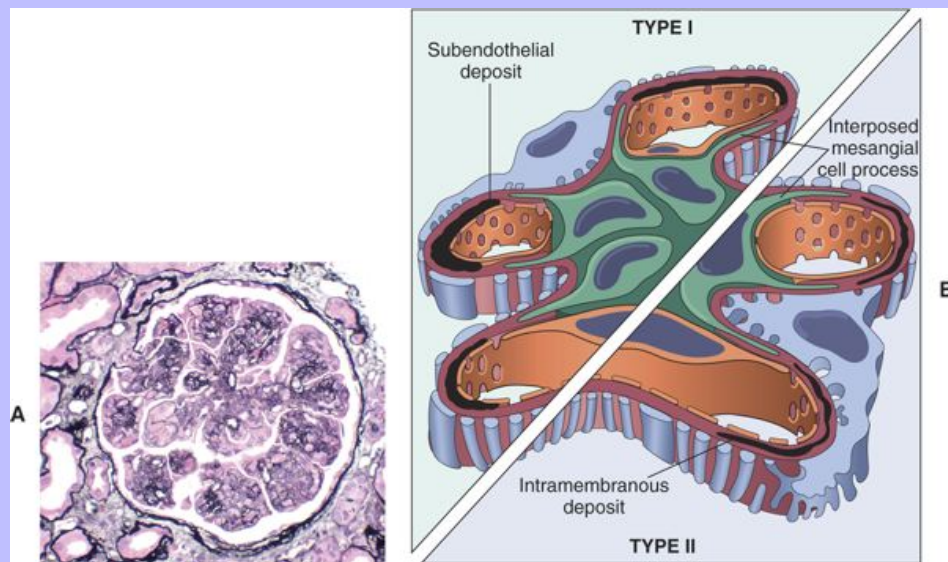

### Proliferative Glomerulonephritis

Proliferative glomerulonephritis is a form of immune-complex glomerular disease characterized by increased cellularity of the glomerular tufts caused by proliferation of glomerular endothelial, epithelial, and mesangial cells and an influx of neutrophils and other leukocytes and involves both the capillary loops and the mesangium (Fig. 11-21, A).

636

637

**Fig. 11-20 Membranoproliferative glomerulonephritis, glomerulus, kidney. A,** Note the increased mesangial matrix and thickened and focally split basement membranes (*stained black*). The glomeruli are also infiltrated by leukocytes (not visible here). Silver reticulum stain. **B,** Schematic representation of patterns in the two types of membranoproliferative glomerulonephritis. In type I there are subendothelial deposits; type II is characterized by intramembranous dense deposits (dense deposit disease). In both, mesangial interposition gives the appearance of split basement membranes when viewed in the light microscope. (**A** and **B**, From Cotran RS, Rennke H, Kumar V: The kidney and its collecting system, ed 7, Philadelphia, 2002, Saunders.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

11.2.2.4.4

### Membranous Glomerulonephritis

Membranous glomerulonephritis is characterized by diffuse glomerular capillary basement membrane thickening because of the presence of subepithelial immunoglobulin deposits, as the predominant change (Figs. 11-21, B; 11-19; and 11-20). These deposits are separated by protrusions of glomerular basement membrane matrix that eventually encompass these deposits. Following removal of the deposited material, cavities are left in the glomerular basement membrane and later these fill with glomerular basement membranelike material, which results in sclerotic change within the glomerular tuft. This is characterized by increased deposition of (periodic acid–Schiff) positive material and a lesser amount of fibrosis. This variation is the most common form of immune-complex glomerulonephritis in cats.

11.2.2.4.5

### Membranoproliferative Glomerulonephritis

Membranoproliferative glomerulonephritis (mesangioproliferative, mesangiocapillary) is characterized by hypercellularity following proliferation of glomerular cells and thickening of the capillary basement membrane and mesangium (Figs. 11-19 and 11-20). This variant appears to be the most common morphologic form of immune-complex glomerulonephritis in the dog. Light microscopy fails to detect differences evident by immunofluorescent and electron microscopy. The latter allows subcategorization of membranoproliferative glomerulonephritis into type I and type II (Fig. 11-19). Type I is characterized by the presence of subendothelial deposits and a granular pattern following deposition of C3 and lesser quantities of IgG, C1q, and C4. Type I disease appears to be secondary to deposition of circulating immune complexes. Type II is also referred to as dense deposit disease because electron-dense material of unknown composition, and smaller quantities of C3, form an irregular deposit within the subendothelial space and the lamina densa. Type II disease appears to be a form of autoimmune disease, but its pathogenesis is not clear.

Several other changes in the glomerulus and Bowman's capsule usually accompany the lesions discussed previously. These changes include adhesions between the epithelial cells of the glomerular tuft and Bowman's capsule (synechiae; singular = synechia), hypertrophy and hyperplasia of the parietal epithelium lining Bowman's capsule, deposition of fibrinogen and fibrinous thrombi in glomerular capillaries, secondary to or as a result of the glomerular damage, and dilated renal tubules filled with homogeneous proteinaceous fluid. An increase in mesangial matrix is often also present. If the damage is mild and the cause is removed, glomeruli can heal without obvious or with minimal residual lesions. However, if the lesion is severe and prolonged, subacute to chronic glomerular changes develop. Bowman's capsule can become thickened, hyalinized, and reduplicated. In severe cases, proliferation of parietal epithelium, an influx of monocytes, and deposition of fibrin can occur within Bowman's capsule, resulting in the formation of a semicircular, hypercellular, intraglomerular lesion known as a glomerular crescent (Fig. 11-21, C). The glomerular crescent can also undergo fibrosis, and if Bowman's capsule ruptures, glomerular fibrosis can become continuous with interstitial fibrosis. Interstitial and periglomerular fibrosis, foci of interstitial lymphocytes, and plasma cells and glomerulosclerosis may be present in chronic glomerulonephritis.

637

638

**Fig. 11-21 Types of glomerulonephritis.** **A**, Proliferative glomerulonephritis, pig. The lesion is characterized principally by hypercellularity of the glomerulus due to increased numbers of mesangial cells. H&E stain. **B**, Membranous glomerulonephritis, dog. The lesion is characterized by generalized hyaline thickening of glomerular capillary basement membranes. It can occur in dogs with dirofilariasis. H&E stain. **C**, Membranoproliferative glomerulonephritis, horse. Membranoproliferative glomerulonephritis has histologic features of both proliferative glomerulonephritis and membranous glomerulonephritis. Abundant periglomerular fibrosis surrounds this hypercellular glomerulus (mesangial cells). Mesangial matrix is prominent in the top-right area of the glomerulus. H&E stain. **D**, Glomerulosclerosis, dog. Note the hypocellularity, shrinkage, and hyalinization due to an increase in fibrous connective tissue and mesangial matrix and almost complete loss of glomerular capillaries. In glomerulosclerosis (the end stage of chronic glomerulonephritis), glomeruli are essentially nonfunctional. H&E stain. (**A** and **C**, Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B** and **D**, Courtesy Dr. S.J. Newman, College of Veterinary Medicine, University of Tennessee.)

### 11.2.2.5 GLOMERULOSCLEROSIS

In chronic glomerulonephritis, severely affected glomeruli shrink and become hyalinized because of an increase in both fibrous connective tissue and mesangial matrix and a loss of glomerular capillaries (Fig. 11-21, D). These glomeruli are hypocellular and essentially nonfunctional. This process is referred to as glomerulosclerosis. Glomerulosclerosis can be diffuse, involving all glomeruli, or multifocal. In addition, glomerulosclerosis can involve a whole glomerular tuft (global) or only portions of the tuft (segmental) thus appearing as a nodular or segmental hyalinized thickening in affected glomeruli. Because tubules receive their blood supply from the vasa recta, derived from the glomerular efferent arteriole, glomerulosclerosis reduces the blood flow through the vasa recta, thus decreasing oxygen tension in the tubules. The resulting hypoxia is responsible for tubular epithelial cell death via apoptosis and results in tubular atrophy and flattening of the remaining tubular epithelium. In addition, chronic proteinuria often accompanies glomerulosclerosis and has been reported to stimulate tubular epithelial cell loss through apoptosis.

638

639

Numerous factors are associated with and accelerate glomerulosclerosis. These factors include the following:

1. Unrestricted protein in the diet
2. Increased glomerular capillary pressure in functional glomeruli
3. Cytokines
4. Platelet-derived growth factors

These factors have the following effects:

1. Alter cellular components of the functional glomerular tufts
2. Cause hypertension and transglomerular hyperfiltration with resultant damage to endothelium
3. Activate mesangial cells to proliferate
4. Increase mesangial matrix production
5. Accelerate visceral epithelial cell loss, which allows synechiae (i.e., adhesions between visceral and parietal epithelial cell layers in the glomerulus) to form

Glomerulosclerosis is not only the end-stage of glomerulonephritis but also can develop in any chronic disease in which severe damage to nephrons or loss of nephron function occurs. Mild multifocal glomerulosclerosis of unknown cause is often an incidental finding in aged animals. Glomerulosclerosis has been reported occasionally in animals with hypertension and diabetes mellitus. In these cases, global or nodular eosinophilic glycoprotein material (hyaline material) is deposited in the glomerular mesangium.

### 11.2.2.6 GLOMERULAR AMYLOIDOSIS

Amyloid, an insoluble fibrillar protein with a  $\beta$ -pleated sheet conformation, is produced after incomplete proteolysis of several soluble amyloidogenic proteins. Amyloid deposits in patients with plasma cell myelomas or other B-lymphocyte dyscrasias (called AL amyloidosis) are composed of fragments of the light (L) chains of immunoglobulins. In domestic animals, spontaneously occurring amyloidosis is usually an

## Pathologic Basis of Veterinary Disease, 4th Edition

---

example of what is called reactive amyloidosis (AA amyloidosis). This form of the disease is often associated with chronic inflammatory diseases; the amyloid deposits are composed of fragments of a serum acute-phase reactant protein called serum amyloid-associated (SAA) protein. Amyloid fibrils from either source are deposited in tissue along with a glycoprotein called amyloid P-component.

Glomeruli are the most common renal sites for deposition of amyloid in most domestic animal species, although the medullary interstitium is a common site in cats, particularly in Abyssinian breeds. Renal amyloidosis commonly occurs in association with other diseases, particularly chronic inflammatory or neoplastic diseases. However, idiopathic renal amyloidosis (i.e., amyloidosis in which an associated disease process is not recognized) is also described in dogs and cats. The underlying pathogenic mechanisms of idiopathic renal amyloidosis are not known. In a recent study, 23% of dogs that presented with proteinuria had renal amyloidosis. A hereditary predisposition for the development of reactive amyloidosis (AA) has been found in Abyssinian cats and Chinese Shar-Pei dogs. A familial tendency is suspected in Siamese cats, English foxhounds, and beagle dogs. In cattle, renal amyloidosis is nearly always due to chronic systemic infectious disease. Glomerular amyloidosis is responsible for many cases of protein-losing nephropathy in animals that have notable proteinuria and uremia. It can, like immune-complex glomerulonephritis, result in the nephrotic syndrome. Long-standing glomerular amyloidosis results in diminished renal blood flow through the glomeruli and the vasa recta. Such reduced renal vascular perfusion can lead to renal tubular atrophy, degeneration, diffuse fibrosis and in severe cases, renal papillary necrosis. Medullary amyloidosis is usually asymptomatic unless it results in papillary necrosis.

Kidneys affected with glomerular amyloidosis are often enlarged, pale, and increased in consistency, and have a smooth to finely granular capsular surface (Fig. 11-22). Amyloid-laden glomeruli may be visible grossly as fine translucent dots on the capsular surface. Similarly, the cut surface of the cortex can have a finely granular appearance (Fig. 11-22). Treatment of kidneys with an iodine solution, such as Lugol's iodine, in many cases results in red-brown staining of glomeruli, which become purple when exposed to dilute sulfuric acid (Fig. 11-23). This technique provides a rapid presumptive diagnosis of renal amyloidosis. Medullary amyloidosis is usually not grossly recognizable.

Microscopically, glomerular amyloid is deposited in both the mesangium and subendothelial locations. Amyloid is relatively acellular and can accumulate segmentally within glomerular tufts; thus a portion of the normal glomerular architecture is replaced by eosinophilic, homogeneous to slightly fibrillar material (Fig. 11-24, A). When amyloidosis involves the entire glomerular tuft, the glomerulus is enlarged, capillary lumina become obliterated, and the tuft can appear as a large hypocellular, eosinophilic hyaline sphere (Fig. 11-24, B). Amyloid can be present in renal tubular basement membranes, and these membranes are hyalinized and thickened. Additionally, in cases of glomerular amyloid deposition, secondary changes may be present in renal tubules, which are usually markedly dilated, have variably atrophic epithelium, and contain proteinaceous and cellular casts. Amyloid is confirmed microscopically by staining with Congo red stain (Fig. 11-24, C). When viewed with polarized light, amyloid has a green birefringence (Fig. 11-24, D). Loss of Congo red staining after treatment of a section of affected kidney with potassium permanganate suggests the amyloid is AA-amyloid (i.e., of acute-phase reactant protein origin).

639

640

Fig. 11-22 **Amyloidosis, kidney, dog.** Grossly, kidneys affected by amyloid deposition are diffusely tan, waxy (firm), and of normal size or slightly enlarged. Affected glomeruli are not grossly visible in this specimen, unlike in advanced cases of glomerular amyloidosis or chronic glomerulonephritis. In advanced cases of amyloidosis, glomeruli may be visible as pinpoint, glistening, round, cortical foci. In cats and Shar-Pei dogs, amyloid is deposited in the medullary interstitium, not in the glomeruli. There are also multiple foci of medullary crest necrosis (*yellowish-green*). (Courtesy Dr. G.K. Saunders, The Virginia-Maryland Regional College of Veterinary Medicine; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

**Fig. 11-23 Amyloidosis, kidney, transverse section, dog.** On the cut surface of fresh kidney treated with Lugol's iodine followed by dilute sulfuric acid, glomeruli containing amyloid are visible as multiple dark blue dots in the cortex. Lugol's iodine treatment. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

### 11.2.2.7 MISCELLANEOUS GLOMERULAR LESIONS

Glomerular lipidosis, characterized by small aggregates of lipid-laden foamy macrophages in glomerular tufts, is an occasional incidental finding in dogs. A similar but more extensive glomerular lipidosis has been described in cats with inherited hyperlipoproteinemia, which is a generalized disease characterized by hyperchylomicronemia, atherosclerosis, and xanthogranulomas in numerous parenchymatous organs, including the kidneys (see Granulomatous Nephritis). Microscopically, glomeruli contain foamy macrophages, characteristic of glomerular lipidosis, as well as increased mesangium and thickened Bowman's capsule.

An idiopathic renal glomerular vasculopathy and cutaneous vasculopathy occurs in greyhounds. The cause of this disease is unknown, but renal lesions are similar to those seen in disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, and hemolytic-uremic syndrome in human beings. At necropsy, kidneys from affected dogs are swollen and congested and show cortical petechiae (Fig. 11-25, A). Microscopically, numerous glomeruli have segmental or global fibrinous thrombi, hemorrhage, and necrosis (Fig. 11-25, B). At the glomerular vascular pole, the walls of afferent arterioles have fibrin deposits and foci

## Pathologic Basis of Veterinary Disease, 4th Edition

---

of necrosis. Affected greyhounds have multifocal erythematous and ulcerated skin lesions and distal limb edema. Variable systemic signs of uremia often accompany the cutaneous lesions. Thrombocytopenia is frequently seen.

In canine hyperadrenocorticism or as a result of excessive exogenous glucocorticoid therapy, proteinuria often develops. The cause of this lesion is unknown; however, hypertension has been postulated because of its occurrence with increased plasma glucocorticoid concentrations. Glomerular lesions consist of mild mesangial hypercellularity, synechiae, thickened basement membranes, and effacement of epithelial foot processes. Lesions are devoid of immunoglobulin.

Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 11.2.3 DISEASES OF THE TUBULES AND INTERSTITIUM

#### 11.2.3.1 AZOTEMIA AND UREMIA

Assays for plasma or serum concentrations of urea, creatinine, and the nitrogenous waste products of protein catabolism, are routinely used as indices of diminished renal function. The intravascular increase of these nitrogenous waste products is referred to as azotemia. Renal failure can result in the following:

1. Intravascular accumulation of other metabolic wastes, such as guanidines, phenolic acids, and large molecular weight alcohols (example: myoinositol)
2. Reduced blood pH (metabolic acidosis)
3. Alterations in plasma ion concentrations, particularly potassium, calcium, and phosphate
4. Hypertension

641

---

The result of renal failure is a toxicosis called uremia. Uremia can therefore be defined as a syndrome associated with multisystemic lesions and clinical signs because of renal failure.

642

Fig. 11-25 **Vasculopathy, renal (and cutaneous) vasculopathy syndrome, glomerulus, kidney, dog, greyhound.** **A**, The fine white dots in the cortex (both on the capsular and cut surfaces) are glomeruli with extensive glomerular capillary thrombosis. **B**, Necrotic glomerular endothelial cells and extensive glomerular capillary thrombosis (*arrows*) are typical of idiopathic glomerular (and cutaneous) vasculopathy syndrome in greyhound dogs. Fenwick, Virginia Tech.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Nonrenal lesions of uremia identified clinically or at necropsy are useful indicators of renal disease ([Table 11-1](#)). The severity of nonrenal lesions of uremia is dependent on the length of time that the animal has survived in the uremic state. Therefore in acute renal failure, nonrenal lesions are few, whereas in chronic renal failure many lesions can be present. Typically, lesions can be attributed to either of the following:

1. Endothelial degeneration and necrosis, resulting in vasculitis with secondary thrombosis and infarction in a variety of tissues
2. Caustic injury to epithelium of the oral cavity and stomach secondary to the production of large concentrations of ammonia following splitting of salivary or gastric urea by bacteria

Systemic lesions of uremia include the following:

1. Ulcerative and necrotic stomatitis characterized by a brown, foul-smelling, mucoid material adherent to the eroded and ulcerated lingual and oral mucosa; ulcers are most commonly present on the underside of the tongue ([Fig. 11-26](#))
2. Ulcerative and hemorrhagic gastritis in dogs and cats ([Fig. 11-27](#)), often with secondary midzonal mineralization ([Fig. 11-28](#))
3. Ulcerative and hemorrhagic colitis in horses and cattle. Large areas of the gastric or colonic mucosa are often edematous and dark red because of hemorrhage. The gastrointestinal contents can be bloody and smell of ammonia. Microscopically, coagulative necrosis, hemorrhage, and a neutrophilic infiltrate occur in the mucosa. Degeneration, necrosis, and mineralization of the arteriolar intima and media are often present in the gastric mucosa and submucosa ([Fig. 11-28](#)).
4. Fibrinous pericarditis characterized by fine granular fibrin deposits on the epicardium (visceral pericardium)
5. Diffuse pulmonary edema. In the latter, alveoli contain fibrin-rich fluid and often a mild infiltrate of macrophages and neutrophils. This lesion is called uremic pneumonitis. These lesions result secondary to increased vascular permeability from the associated vasculitis.
6. Mucoarthritis characterized grossly by finely granular roughened plaques

**Table 11-1 Nonrenal Lesions of Uremia**

Lesion	Mechanism
Pulmonary edema	Increased vascular permeability
Fibrinous pericarditis	Increased vascular permeability
Ulcerative and hemorrhagic gastritis	Ammonia secretion and vascular necrosis
Ulcerative and necrotic stomatitis	Ammonia secretion in saliva and vascular necrosis
Atrial and aortic thrombosis	Endothelial and subendothelial damage
Hypoplastic anemia	Increased erythrocyte fragility and lack of erythropoietin production in the kidney
Soft-tissue mineralization	Altered calcium-phosphorus metabolism (stomach, lungs, pleura, kidneys)
Fibrous osteodystrophy	Altered calcium-phosphorus metabolism
Parathyroid hyperplasia	Altered calcium-phosphorus metabolism

**Fig. 11-26 Ulcerative glossitis, uremia, tongue, ventral surface, cat.** Bilaterally symmetrical ulcers (*arrows*) are present on the rostralateral borders of the ventral surface of the tongue. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 11-27 Uremic gastritis, stomach (right), dog.** Because of uremia, the stomach wall is hemorrhagic and the contents contain blood and mucus (not shown here). Note the edematous mucosal thickening (*arrow*). (Courtesy Dr. A. Confer, College of Veterinary Medicine, Oklahoma State University.)

In the uremic animal, focal subendothelial degeneration can occur in the left atrial endocardium and less frequently in the endothelial surface of the proximal aorta and pulmonary trunk. Mucoarteritis in conjunction with loss of the anticoagulant antithrombin III by glomerular leakage is conducive to the formation of large mural thrombi at these sites.

643

Chronic renal failure often results in hematologic and biochemical alterations. In the diseased kidney, production of erythropoietin, a stimulant of erythropoietic maturation, is reduced and contributes to nonregenerative anemia, as does uremia-associated increased erythrocytic fragility. Most animals in renal failure have hyperphosphatemia and low to normal calcium levels, although variations exist depending on species and stage of the disease. Alterations in calcium-phosphorus metabolism in the uremic animal are a hallmark of chronic renal failure and result from a complex set of events as outlined below:

1. When the glomerular filtration rate is chronically reduced to less than 25% of normal, phosphorus is no longer adequately secreted by the kidneys and hyperphosphatemia results.
2. Because of the mass law interactions between serum calcium and phosphorus, ionized calcium concentration in serum is reduced as a result of precipitation of calcium and phosphorus.
3. Reduced ionized serum calcium stimulates parathyroid hormone secretion, causing calcium release from the readily mobilizable calcium stores in the bone and from osteoclastic bone resorption.
4. These changes in calcium-phosphorus metabolism are made more severe by the reduced ability of the diseased kidneys to hydroxylate 25-hydroxycholecalciferol to the more active 1,25-dihydroxycholecalciferol (calcitriol), resulting in decreased intestinal absorption of calcium.
5. Calcitriol production is further inhibited by hyperphosphatemia.
6. In addition, calcitriol normally suppresses parathyroid hormone secretion; therefore reduced calcitriol production further increases parathyroid hormone secretion. With time, these events lead to parathyroid chief cell hyperplasia (renal secondary hyperparathyroidism), fibrous osteodystrophy (renal osteodystrophy), and soft tissue calcification.
7. Renal secondary hyperparathyroidism is further thought to perpetuate and enhance renal disease by stimulating nephrocalcinosis (Fig. 11-29), the process by which renal tubular epithelium is damaged by an increase in intracellular calcium. Calcium is precipitated in mitochondria and in tubular basement membranes.
8. Soft tissue calcification associated with uremia occurs in numerous sites and represents both dystrophic and metastatic calcification.

643

644

**Fig. 11-28 Uremic gastritis, stomach, dog.** **A**, There is accentuation of the gastric rugae and calcification in the deep mucosa. **B**, The mucosa has laminar mineralization of gastric glands (*arrow*). von Kossa stain. (**A**, Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University. **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

A characteristic lesion of uremic mineralization, particularly in dogs, is calcification of the subpleural connective tissue of the cranial intercostal spaces (Fig. 11-30). These lesions are white-gray granular pleural thickenings with a horizontal “ladderlike” arrangement. The intercostal muscles are only superficially calcified. Patchy or diffuse pulmonary calcification of the lungs results in their failure to collapse, areas of paleness, and mild to moderate firmness and crunchiness and can occur occasionally in conjunction with the lesions of uremic pneumonitis. Microscopically the alveolar septa are calcified and can focally rupture, causing small emphysematous bullae. Although usually not visible at necropsy, calcification occurs in the kidneys. The kidneys can be gritty when cut because of calcification of tubular basement membranes, Bowman's capsules, and necrotic tubular epithelium, especially in the medulla and inner cortex. The gastric wall can be gritty when cut because of calcification of the inner and middle layers of the mucosa, and the submucosal arterioles. Necrotic arterioles (uremic vasculitis) throughout the body are particularly susceptible to dystrophic calcification following uremic injury.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Animals that die of acute renal failure often do so because of the cardiotoxicity of elevated serum potassium, metabolic acidosis, and/or pulmonary edema. Hyperkalemia results from decreased filtration, decreased tubular secretion, and decreased tubular sodium transport. Cell lysis and the extracellular shift of fluid in acidic environments also contribute to the increased serum potassium concentrations.

**Fig. 11-29 Nephrocalcinosis, kidney, dorsal section, dog.** Note the white streaks in the cortex and medulla attributable to mineralization of the interstitium, basement membranes, and tubules. This lesion results from diseases that increase plasma calcium concentrations (e.g., hyperparathyroidism). Renal tubular epithelium is damaged by an increase in intracellular calcium, which is initially precipitated in mitochondria and tubular basement membranes. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 11-30 Thoracic cavity, parietal pleura, cat.** Horizontally oriented streaks (*arrows*) of mineral (intercostal mineralization) are present in the subpleural intercostal connective tissue as a result of chronic uremia. (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

### 11.2.3.2 ACUTE RENAL FAILURE

When renal functional capacity is abruptly impaired (loss of 75%), such that the kidneys fail to carry out their normal metabolic and endocrine functions, acute renal failure can ensue. It is important to remember that the glomerulus, tubules, collecting ducts, and capillary blood supply in each nephron are closely interrelated, both anatomically and functionally. Alterations in tubular structure or function influence glomerular structure and function and vice versa. For example, necrosis or atrophy of renal tubules results in loss of function of the affected nephrons and secondary atrophy of the glomerulus. In addition, because most of the capillary blood supply to tubules is through postglomerular capillaries, a reduction in glomerular blood flow consequently reduces the blood supply to the tubules.

644

645

Acute renal failure can be caused by prerenal (compromised renal perfusion), intrarenal (compromised kidney function), or postrenal (obstruction of the urinary tract) factors. Prerenal factors include reduced renal blood flow, whether secondary to circulatory collapse (shock, severe hypovolemia) or local obstruction of vascular supply (thrombus or lodgment of embolus).

Prerenal and intrarenal factors are most responsible for episodes of acute renal failure, with prerenal azotemia and ischemic tubular damage actually being a continuum. Intrarenal disease can target tubules by three main mechanisms:

1. Ascending disease, such as pyelonephritis
2. Intraluminal toxic metabolites
3. Ischemia

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Postrenal obstructive diseases will be discussed in the lower urinary tract section.

Acute renal failure occurs when the kidney fails to excrete waste products and to maintain fluid and electrolyte homeostasis. The four main pathologic alterations in acute renal failure are as follows:

1. Decreased ultrafiltration
2. Intratubular obstruction
3. Fluid back leak
4. Intrarenal vasoconstriction

These can occur following many insults, including the following:

1. Decreased renal perfusion
2. Decreased glomerular filtration
3. Ischemic tubular damage
4. Toxic tubular damage
5. Obstructive renal tubular damage
6. Tubulointerstitial inflammation, edema, or fibrosis

### 11.2.3.3

#### ACUTE TUBULAR NECROSIS

Acute tubular necrosis is the single most important cause of acute renal failure. Acute tubular degeneration and necrosis, often referred to as nephrosis, lower nephron nephrosis, tubular nephrosis, tubular dysfunction, or acute cortical necrosis, is principally the result of nephrotoxic damage to the renal tubular epithelial cells or ischemia.

Nephrotoxins preferentially damage kidneys because 20% to 25 % of cardiac output goes to the kidney and because of the concentration of the toxin or its metabolites within the renal tubular lumens. Nephrotoxins can directly damage renal epithelial cells, particularly those of the proximal convoluted tubules, following their intracellular conversion to reactive metabolites. Additionally, reactive metabolites in the tubular filtrate or less commonly in the intertubular capillaries can cause renal tubular epithelial necrosis following reabsorption or diffusion, respectively. Additionally, many of these metabolites can indirectly stimulate vasoconstriction and ischemia, which further compromises renal function. In nephrotoxin-associated ischemia, one of the first events in renal tubular cell damage is altered ion transport at the luminal surface. This process results in decreased sodium absorption and increased sodium ions in the lumens of the distal tubules, which stimulate the renin-angiotensin mechanism, causing vasoconstriction and reduced blood flow that result in ischemia and tubular cell damage. Nephrotoxins usually do not damage the tubular basement membranes, and thus regeneration (repair) of tubules can occur in an orderly and expeditious manner. The intact basement membrane acts as a scaffold over which regenerating epithelial cells may slide. Exposure to a variety of nephrotoxins, either from the vasculature (including certain chemicals [glycoaldehyde, glycolic acid and glyoxylic acid] or excessive metabolites, such as glycogen or fat) or from the tubular lumen

## Pathologic Basis of Veterinary Disease, 4th Edition

---

(including certain antibiotics [aminoglycosides], pigments [hemoglobin], metals [lead], or chemicals [ethylene glycol–induced calcium oxalate crystals]), cause cells to undergo degeneration followed by necrosis and desquamation into the tubular lumen. Cell death results from decreased adenosine triphosphate (ATP) production, which is central to many of the secondary metabolic derangements, including calcium ion influx, purine depletion, metabolic acidosis, and generation of oxygen radicals. Increased intracellular calcium is associated with degenerative changes in renal tubular cells, smooth muscle cells, and mesangial cells ([Table 11-2](#)). Oxygen radicals activate phospholipase, which subsequently increases membrane permeability. Because mitochondrial respiration is disrupted, further cell membrane damage occurs.

Notably reduced renal perfusion from any cause can result in tubular necrosis. Severe hypotension associated with shock results in preglomerular vasoconstriction and reduced glomerular filtration. The resulting renal ischemia can produce sublethal tubular cell injury and dysfunction or cause cell death by necrosis or apoptosis. Following less severe insults and within different portions of the renal tubule, apoptosis may occur in lieu of necrosis.

Modified from Chew D, DiBartola S: Diagnosis and pathophysiology of renal disease. In Ettinger SJ, editor: *Textbook of veterinary internal medicine*, ed 3, vol 2, Philadelphia, 1989, Saunders.

The apoptotic pathway can be triggered by the following:

1. Binding of ligands to the tumor necrosis factor (TNF) superfamily
2. Deficiency of cellular growth factors
3. Imbalance between proapoptotic and antiapoptotic oncogenes
4. Alteration of other mediators of apoptotic signaling pathways, such as reactive oxygen metabolites, caspases, and ceramide

Proximal tubular epithelium has a microvillous border, which amplifies absorptive surface area and cellular junctional complexes that structurally polarize the cell such that membrane phospholipids and specialized proteins remain in the appropriate domains. The integrity of these cellular structures is critical to absorption and secretion. Early structural changes following ischemic insult include formation of apical blebs, loss of brush border, loss of cellular polarity, disruption of tight junctions, and sloughing of cells, which result in intratubular cast formation (Figs. 11-31 and 11-32).

Damage to the cellular cytoskeleton modifies cell polarity, cell-to-cell interactions and cell-matrix interactions. Initially, ischemic damage modifies cell polarity by disruption of the terminal web and

## Pathologic Basis of Veterinary Disease, 4th Edition

disassembly of the microvillar actin cores. This is followed by conversion of G actin to F actin and its redistribution from the apical cell component to form diffuse aggregates throughout the cytoplasm (Figs. 11-33 and 11-34). Cells are attached to each other by junctional complexes, tight junctions and adherens junctions, and to the extracellular matrix by integrins. Several mechanisms contribute to tight junction disruption, which is manifested as alteration in cellular permeability and cell polarity. The contributing mechanisms include redistribution of membrane lipids and proteins, such as  $\text{Na}^+ \text{K}^+ \text{-ATPase}$ , to the apical membrane following alteration of the actin cytoskeleton and redistribution of integrins to the apical cell surface, such that cell desquamation occurs. The former results in deranged sodium handling by the proximal tubular cell.

Animals with severe tubular necrosis have accompanying functional derangements of vascular, tubular, and/or glomerular origin. Vascular derangements include the following:

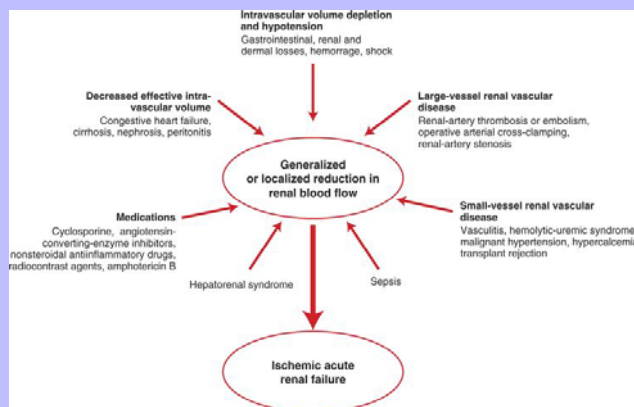

1. Afferent arteriolar constriction
2. Efferent arteriolar dilation
3. Loss of autoregulation of renal blood flow

Prolonged ischemia can produce a paradoxical response of the autoregulatory system, where increased glomerular capillary resistance from tubular fluid stasis results in activation of afferent arteriolar vasoconstriction. Decreased production of or response to vasodilative factors, such as prostaglandin and atrial natriuretic peptide, also contribute. Afferent arteriole vasoconstriction, back leak of fluid, and tubular obstruction account for decreased glomerular filtration rate (GFR) (Fig. 11-35).

646

647

**Fig. 11-31 Schematic diagram of ischemic renal failure.** A wide spectrum of clinical conditions can result in a generalized or localized reduction in renal blood flow, thus increasing the likelihood of ischemic acute renal failure. The most common condition leading to ischemic acute renal failure is severe and sustained prerenal azotemia. Kidney ischemia and acute renal failure are often the result of a combination of factors. (Redrawn from Thadhani R, Pascual M, Bonventre JV: N Engl J Med 334(22):1448-1460, 1996.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Tubuloglomerular feedback is the mechanism by which GFR is matched to the solute load and the solute handling characteristics of the tubules. Because of altered sodium handling, increased levels reach the macula densa, and activation of the renin-angiotensin system occurs. This is followed by intrarenal vasoconstriction, particularly affecting outer cortical nephrons, and results in decreased glomerular blood flow, decreased filtration, and reduced formation of urine. Tubular metabolic demand is concurrently reduced. Tubular fluid flow can be negligible due to renal tubular epithelial cell swelling and tubular cast formation, and there may be accompanying back leak of glomerular filtrate, as a result of either loss of integrity of the tight junctions or an altered distribution of  $\beta$ -1 integrins, such that cell sloughing and tubular obstruction result. Fluid present in the interstitium further increases intratubular pressure and compromise of the intertubular capillaries. A vicious cycle ensues.

If the insult to the renal tubules is not lethal and is removed, some forms of acute tubular necrosis are reversible. The success of reparative regeneration is affected by several variables including severity of necrosis:

1. Single cell loss (apoptosis) from the tubular epithelial lining is handled efficiently by adjacent viable tubular epithelial cells, which by mitotic division, fill the epithelial gap. The cells that are lost slough into the lumen to form cellular casts within the lumens of renal tubules (Fig. 11-36).
2. More severe generalized loss of tubular epithelial lining cells is repaired by proliferation of the remaining viable epithelial cells over an intact tubular basement membrane to form a low cuboidal rather than a mature columnar epithelial lining. This appears as an ectatic proximal tubule. Restitution of renal function eventually results, despite the presence of replacement low cuboidal epithelium, which is not identical to the tubular lining cell (with microvilli) present before the injury. The exact mechanism of this return to function is not entirely known. The main determinant of this regenerative ability is the viability of tubular basement membranes, which are retained more consistently following toxic rather than ischemic insults.

647

648

**Fig. 11-32 Schematic diagram of the effect of ischemia on cell structure and function.** A polarized renal proximal tubule cell with a well-developed actin cortical cytoskeleton is shown on the left. Also shown is attachment to the extracellular matrix via integrins. Following ischemic injury there is extensive disruption, redistribution, and aggregation of the actin cytoskeleton resulting in loss of microvilli structure, blebbing of microvilli into the lumen, detachment of cells from the extracellular matrix, and opening of junctional complexes (JC). Injured proximal tubule cells can undergo primary repair and recover directly into a polarized epithelial cell. Cells can also go through an undifferentiated phase followed by redifferentiation, or cells can die either rapidly via necrosis or in a much slower programmed fashion known as apoptosis. The primary route of cellular repair involves direct recovery. The percentage of cells reverting to an undifferentiated state or dying depends on the severity of the injury and the location within the kidney. FA, Focal adhesions; TW, terminal web. (Redrawn from Molitoris BA, Marrs J: *Am J Med* 106:583-592, 1999.)

Because the regenerative process is reliant on many factors for its success, things often go awry. Examples include the following:

1. Focal loss of basement membrane scaffolding allows for a bulge defect to occur where the regenerative population of proliferating tubular epithelial cells coalesce to form well-differentiated syncytial cells (giant cells) at certain levels of the tubule.
2. Regenerative epithelial cells fail to regain all cytoplasmic structural aspects of the original columnar epithelial cells (e.g., microvilli and luminal enzymes) because of a failure to fully differentiate, and thus function may be affected.
3. If there is excessive tubular epithelial loss, the potential for regeneration is lost and repair proceeds by replacement fibrosis and scarring.
4. Reperfusion is necessary for cell viability following ischemia, but reperfusion injury occurs when activated endothelial cells produce proinflammatory mediators such as reactive oxygen species, proteolytic enzymes, and cytokines, which result in further renal injury.

Recent evidence indicates that epidermal growth factor secreted by distal convoluted tubules mediates the tubular repair process. The sequence of events in tubular regeneration following necrosis have been well documented in experimental model systems using mercuric chloride in mice, rats, and rabbits. In that system, morphologic evidence of regeneration of proximal convoluted tubules is seen within 3 days after a toxic dose. At this time, basement membranes are partially covered with low cuboidal to flattened and elongated epithelial cells that are more basophilic than normal because of the increased concentrations of cytoplasmic ribosomes and rough endoplasmic reticulum producing protein for repair. Nuclei are hyperchromatic and mitotic figures are present. Regenerating tubules do not function normally because they lack both a brush border and normal tubular membrane function, and this is evident clinically as polyuria. Normal-appearing tubular epithelium subsequently reappears between 7 and 14 days after toxin exposure. Normal renal structure without residual evidence of tubular damage is restored between 21 and 56 days after exposure to the nephrotoxin. Similar time frames for tubular regeneration have been described through sequential renal biopsies from human patients naturally exposed to inorganic mercury and in experimental systems using other nephrotoxins.

**Fig. 11-33 Schematic diagram of the effect of ischemia on the actin cytoskeleton and the cytoskeletal-surface membrane interactions in proximal tubule cells.** During ischemia, alterations in the actin cytoskeleton involve disruption of the actin cytoskeleton with redistribution and aggregation of actin throughout the cytoplasm. Consequently, notable alterations occur in cytoskeletal-surface membrane interactions. Loss of cell-cell adhesion, cell-matrix adhesion, and polarity of surface membrane proteins during ischemia play a role in the diminished glomerular filtration rate that is the hallmark of ischemic acute renal failure. (Redrawn from Sutton TA, Molitoris BA: *Sem Nephrol* 18(5):490-497, 1998.)

The alternative to regeneration is tubular loss, and this can occur following either an ischemic insult or exposure to a limited number of nephrotoxins. The ultimate result is replacement fibrosis/scarring. This is seen most commonly if:

1. The toxin is not removed.
2. The basement membrane does not remain intact.
3. Adequate tubular epithelium does not survive the toxic dose to allow for complete repair.

**Fig. 11-34 Schematic diagram of the actin cytoskeleton and the cytoskeletal-surface membrane interactions in proximal tubule cells.** Microvillar F-actin filaments extend into the apical actin network termed the terminal web (TW) and are bound together by villin and attached to the surface membrane by myosin and ezrin to form the structural core of the apical microvilli. The actin cytoskeleton associates with junctional complexes involved in cell-cell interactions, including the tight junction and the adherens junction. More detailed schematics of the tight junction (TJ) and the adherens junction (AJ) appear to the right and demonstrate the interaction of F-actin filaments with TJ and AJ protein complexes. OC represents occludin in the schematic of the TJ, and E-CAD represents E-cadherin in the schematic of the AJ. The cortical actin network associates with surface membrane proteins, such as the sodium-potassium adenosinetriphosphatase, which is demonstrated by the detailed schematic to the lower right. Ank represents ankyrin in this schematic. Finally the actin cytoskeleton associates with structures involved in cell-matrix interactions, including focal adhesions (FA). F-actin filaments (stress fibers) possibly bundled together by myosin II associate with a protein complex at sites where integrins bind to the extracellular matrix. (Redrawn from Sutton TA, Molitoris BA: *Sem Nephrol* 18(5):490-497, 1998.)

A characteristic histologic lesion of ischemic tubular necrosis is disruption of the tubular basement membranes, referred to as tubulorrhexis (Fig. 11-37). Tubular repair in these kidneys is imperfect because

The diagram illustrates three mechanisms of glomerular hypertension:

- Afferent arteriole vasoconstriction:** Shows the afferent artery constricted (narrowed), leading to increased pressure in the glomerulus.
- Back leak:** Shows the efferent artery constricted (narrowed), leading to increased pressure in the glomerulus.
- Tubular obstruction:** Shows the collecting duct obstructed (blocked), leading to increased pressure in the glomerulus.

Chapter 11 Urinary System Page 67 of 146

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The microscopic appearance of kidneys with acute tubular necrosis can be variable, depending on the following:

1. The severity of the injury
2. The duration of exposure to the damaging agent
3. The length of time between the injury and death

Initially, tubular necrosis is randomly distributed in nephrons, but the proximal convoluted tubules are most severely affected (Fig. 11-38). Prolonged ischemia can produce necrosis of epithelium of the proximal and distal convoluted tubules, the loops of Henle, and the collecting ducts throughout the cortex, and to a lesser extent, the medulla. Glomeruli are resistant to ischemia and often remain morphologically normal, even when ischemia is prolonged. Initially, proximal tubular epithelium is swollen, and the cytoplasm is vacuolated or granular and intensely eosinophilic, all features indicative of coagulation necrosis. In such cells, the nuclear changes are pyknosis, karyorrhexis, or karyolysis. Necrotic tubular epithelium is subsequently desquamated into tubular lumens resulting in dilated, notably hypocellular tubules that contain necrotic cellular debris and hyalinized or granular casts.

Acute tubular necrosis induces clinical oliguria (decrease in urine production) or anuria (absence of urine production) by one or several mechanisms. These mechanisms include the following:

1. Leakage of tubular ultrafiltrate from damaged tubules across disrupted basement membranes into the renal interstitium
2. Intratubular obstruction resulting from desquamated necrotic epithelium

The latter mechanism is less well accepted, but both mechanisms result in decreased glomerular filtration rate.

The balance of this section will deal with specific disease processes that produce acute tubular necrosis and include the following:

- Pigments
  - Hemoglobin/myoglobin
  - Bile/bilirubin
- Heavy metals
- Antibiotics
  - Aminoglycosides
  - Oxytetracycline
  - Amphotericin B
  - Sulfonamides

- Monensin
- Nonsteroidal antiinflammatory drugs
- Fungal toxins
- Plant toxins
- Antifreeze (ethylene glycol)
- Vitamins
- Hydrocarbons
- Bacterial toxins

A set of events leading to ischemic tubular necrosis frequently occurs in hypoperfused kidneys complicated by hemoglobinuria or myoglobinuria. Hemoglobinuria accompanies episodes of hemoglobinemia seen secondary to severe intravascular hemolysis as observed in the following:

1. Chronic copper toxicity in sheep
2. Leptospirosis or babesiosis in cattle
3. Red maple toxicity in horses
4. Babesiosis or autoimmune hemolytic anemia in dogs

Fig. 11-36 **Schematic diagram of the effects of ischemia and reperfusion.**

After ischemia and reperfusion, morphologic changes occur in the proximal tubules, including loss of the brush border, loss of polarity, and redistribution of integrins and sodium-potassium adenosinetriphosphatase to the apical surface. Calcium, reactive oxygen species, purine depletion, and phospholipases probably have a role in these changes in morphology and polarity and in the subsequent cell death that occurs as a result of necrosis and apoptosis. There is a sloughing of viable and nonviable cells into the tubular lumen, resulting in the formation of casts and luminal obstruction and contributing to the reduction in the glomerular filtration rate. The severely damaged kidney can completely restore its structure and function. Spreading and dedifferentiation of viable cells occur during recovery from ischemic acute renal failure, which duplicates aspects of normal renal development. A variety of growth factors probably contribute to the restoration of a normal tubular epithelium. (Redrawn from Thadhani R, Pascual M, Bonventre JV: N Engl J Med 334(22):1448-1460, 1996. Color from Molitoris BA, Finn WF, editors: Acute renal failure: a companion to Brenner and Rector's the kidney, Philadelphia, 2001, Saunders.)

**Fig. 11-37 Schematic diagram of acute tubular necrosis, kidney, proximal tubules.** Acute tubular necrosis results from a nephrotoxin or ischemia. **A**, Both insults cause acute necrosis characterized by cellular swelling, pyknosis, karyorrhexis, and karyolysis. **B**, Subsequent to nephrotoxic necrosis, there is sloughing of necrotic epithelium into the tubular lumina. The basement membranes remain intact and act as a scaffold for **(C)** tubular epithelial regeneration to occur. **D**, Ischemia may result in tubulorrhexis. Necrotic epithelial cells slough into the tubular lumen, the basement membrane is disrupted, macrophages infiltrate, and fibroblasts proliferate. **E**, Fibrosis with tubular atrophy results.

Myoglobinuria accompanies acute rhabdomyolysis as occurs in any extreme necrosis of muscle as seen with the following:

## Pathologic Basis of Veterinary Disease, 4th Edition

1. Azoturia ("Monday morning disease") of horses
2. Capture myopathy of exotic or wild animals
3. Severe direct trauma to muscle (i.e., traffic accident)

In these diseases, serum concentrations of hemoglobin or myoglobin are increased. These products pass into the glomerular filtrate, producing greatly increased intraluminal concentrations that cause hemoglobinuric nephrosis or myoglobinuric nephrosis. Hemoglobin attaches to a carrier haptoglobin for transportation, but the latter is too big to pass through the glomerulus. Hemoglobin is not excreted in the urine until supplies of the carrier molecule are depleted and hemoglobin becomes free in the plasma. Myoglobin does not use a carrier protein for transportation, and because it is a small molecule, excesses pass through the glomerular filter and are excreted in the urine. Hemoglobin and myoglobin are not nephrotoxic in themselves, and intravenous infusions of these compounds into healthy animals produce no recognizable lesions. However, large concentrations of hemoglobin or myoglobin in the glomerular filtrate can increase the tubular necrosis that occurs as a result of renal ischemia. In some of the diseases described previously (e.g., chronic copper toxicity in sheep, rhabdomyolysis in horses), affected animals often have renal ischemia secondary to hypovolemic shock or severe anemia. Hemoglobinuria and myoglobinuria can have an additive deleterious effect on tubular epithelium already undergoing ischemic necrosis.

**Fig. 11-38 Acute tubular necrosis, kidney, proximal tubules, cat.** The lesion is characterized by coagulation necrosis of tubular epithelial cells (*arrows*), as demonstrated by nuclear karyolysis and intratubular nuclear and proteinaceous debris. Note that the nuclei, chiefly of endothelial cells of intertubular capillaries and fibroblasts are viable, which differentiates this lesion from an infarct in which all cells are dead. H&E stain. *Inset:* Normal proximal tubules, kidney. In this example, the proximal tubular epithelial cells lack both the nuclear and cytoplasmic changes characteristic of coagulation necrosis, as demonstrated in the main figure. H&E stain. (**Figure** and **Inset**, Courtesy Dr. S.J. Newman, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

At necropsy, the renal cortices of animals with severe hemoglobinuria or myoglobinuria are diffusely stained red-brown to blue-black and have intratubular hemoglobin or myoglobin casts (Figs. 11-39 and 11-40).

These hemoglobin casts appear as a red-black stippling of the external surface and continue into the cortex as radially oriented, dark red streaks (Fig. 11-39, A). The medulla is diffusely dark red or has patchy red streaks.

Classically, kidneys from sheep with chronic copper toxicity are diffusely, uniformly and strikingly

652

blue-black and described as “gunmetal blue.” Microscopically, proximal tubular epithelial degeneration and necrosis are severe and tubular lumens are filled by abundant orange-red granular refractile material, the characteristic appearance of a heme compound (Fig. 11-39, B).

653

**Fig. 11-39 Hemoglobinuric nephrosis, kidney. A, Dog.** Severe diffuse hemoglobin staining of the cortex and medulla is secondary to hemoglobinemia from an acute intravascular hemolytic crisis. Note the yellow staining (jaundice) of the pelvic fat and the intima of cross sections of the arcuate artery at the corticomedullary junction. **B, Sheep.** Several distal tubules contain hyaline and coarsely granular hemoglobin casts that occurred following intravascular hemolysis (hemoglobinemia) from chronic copper toxicosis. H&E stain. (A, Courtesy Dr. A. Confer, College of Veterinary Medicine, Oklahoma State University. B, Courtesy Dr. A.R. Doster, University of Nebraska; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Also, increased serum concentrations of bilirubin, as in young lambs, calves, and foals with immature hepatic conjugating mechanisms, can be associated with cellular swelling, degeneration, and brown-green pigmentation of the proximal tubular epithelial cells. The term *cholemic nephrosis* has been applied to this lesion; however, its significance is doubtful. Acute tubular necrosis, when seen in association with severe bilirubinemia, the so-called hepatorenal syndrome, probably is not due to bile acid or bilirubin retention per se, but to ischemia from prerenal causes, such as constriction of renal vessels related to shock or catecholamine release.

**Fig. 11-40 Myoglobinuric nephrosis, kidney, horse. A,** Diffuse myoglobin staining of the cortex and medulla (*reddish-brown*) is secondary to myoglobinemia from severe rhabdomyolysis. **B,** Myoglobin casts are present in dilated distal tubules, which are lined by flattened epithelial cells. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B,** Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Nephrotoxic tubular necrosis is caused by several classes of naturally occurring or synthetic compounds ([Table 11-3](#)). Inorganic arsenic and certain heavy metals, including inorganic mercury, lead, cadmium, and thallium, are nephrotoxins. Common sources of heavy metals for oral exposure include herbicides (arsenic), old paints (lead), batteries (lead), automobile components (lead), impure petroleum distillates, and other environmental contaminants. Acute tubular necrosis is due to the following:

1. Damage to membranes of proximal convoluted tubular epithelial cells

653

2. Mitochondrial damage produced by these toxins; damage is often related to the interaction of these metals with protein sulfhydryl groups

654

Cisplatin

In mercury toxicosis, mercuric ions enter the proximal tubular cells both from the luminal side, because the ions are present in the glomerular filtrate, and from the peritubular side, where the mercuric ions diffuse from the capillary blood, traverse the interstitium and tubular basement membrane, and enter the tubular epithelium. Mercuric ions become concentrated in the rough endoplasmic reticulum and cause early tubular changes that include loss of brush borders and dispersion of ribosomes. These changes are followed by mitochondrial swelling and cellular death. Recently, cadmium has been reported to cause cell death in proximal convoluted tubules by apoptosis.

The specific metal involved in toxic tubular injury cannot be identified by the renal lesions alone. The exception is lead toxicity, in which the endothelial and epithelial cells of affected glomeruli and tubules, respectively, sometimes have acid-fast intranuclear inclusions composed of lead-protein complexes (Fig. 11-41).

## Pathologic Basis of Veterinary Disease, 4th Edition

Certain pharmaceutical agents are nephrotoxic and cause acute tubular necrosis when administered at excessive doses or too frequently. Cisplatin, a platinum-containing cancer chemotherapeutic agent, causes tubular necrosis by:

1. Direct tubular damage
2. Reducing renal blood flow via vasoconstriction mediated by the renin-angiotensin mechanism

**Fig. 11-41 Nephrosis, lead toxicosis, kidney, cortex, rat.** Acid-fast intranuclear inclusion bodies (*arrow*) present in the proximal convoluted tubular epithelium are diagnostic of lead poisoning. Acid-fast stain with H&E counterstain. (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

654

Aminoglycoside antimicrobials, such as gentamicin, neomycin, kanamycin, tobramycin, amikacin, and streptomycin are nephrotoxic by means of one of the mechanisms described later. Relative renal toxicity varies among the different aminoglycoside drugs and correlates with the concentration of the compound in the renal cortex. Neomycin, which is highly nephrotoxic, concentrates to the greatest extent in the renal cortex; streptomycin, the least nephrotoxic, does not concentrate appreciably in the renal cortex. Although gentamicin is intermediate in its nephrotoxicity between that of neomycin and streptomycin, tubular damage from gentamicin occurs with some frequency because it is a commonly used drug in veterinary medicine.

655

The susceptibility of animal species to the nephrotoxic effects of these drugs is variable and is related to differences in susceptibility of renal tubules and to differences in the rate of excretion or inactivation of the drug among animal species. Aminoglycosides become concentrated in lysosomes, and their toxic effects occur after release of large concentrations of the drugs from these organelles. Toxic levels of aminoglycosides:

1. Become concentrated in lysosomes

## Pathologic Basis of Veterinary Disease, 4th Edition

---

2. Subsequently escape from lysosomes to accumulate in the cytoplasm
3. Alter tubular cell membrane transport by the inhibition of sodium-potassium-ATPase, causing an intracellular influx of hydrogen, sodium ions, and water
4. Inhibit phospholipase activity so that phospholipids accumulate intracellularly
5. Alter mitochondrial function
6. Inhibit protein synthesis

These biochemical changes are responsible for acute swelling of proximal tubular epithelial cells, mitochondrial swelling, rupture of lysosomes, dilation of endoplasmic reticulum, shedding of the brush border, and cellular death.

Oxytetracycline is occasionally nephrotoxic in cattle and dogs. The mechanism of tubular damage has not been determined, but it is known that large concentrations of tetracycline antibiotics can inhibit protein synthesis in mammals. Renal failure occurs in oxytetracycline toxicosis and is likely the result of tubular obstruction caused by desquamated necrotic tubular epithelium.

Amphotericin B, an antifungal polyene antibiotic, is nephrotoxic by the direct disruption of cellular membranes; this membrane damage interferes with normal cholesterol-lipid interactions and causes potassium ion loss, intracellular hydrogen ion accumulation, acute cellular swelling, and necrosis. These renal changes are not confined to cases of an overdose of the drug but can occur in animals given the recommended therapeutic dosage.

Sulfonamide-induced tubular necrosis, a common entity in years past, occurs infrequently today because the presently used sulfonamides have greater solubility than those used in the past. Sulfonamides produce tubular epithelial cell necrosis most readily in dehydrated animals. Crystals form in tubules and necrosis is caused by direct toxicity to the renal tubular epithelium and to mechanical damage. Fine granular yellow crystalline deposits can be seen grossly in the medullary tubules of affected animals, but the crystalline deposits are dissolved during fixation in aqueous fixatives, such as 10% buffered neutral formalin, and during the processing of tissue for histologic sections.

Monensin is an ionophore antibiotic used as a feed additive to control coccidiosis and stimulate weight gains in poultry and cattle. Horses are particularly susceptible to toxicosis with monensin. Although necrosis of striated muscle is the major lesion of the toxicosis, renal tubular degeneration or necrosis can also be a result of altered ionic transport in renal tubular epithelial cells and possibly due to diminished transport of membrane proteins from the cytosol to the cell membrane.

Ingestion of nonsteroidal antiinflammatory drugs (NSAIDs), such as phenylbutazone, aspirin, carprofen, flunixin meglumine, ibuprofen, and naproxen, have been associated with acute renal failure in small animals, especially dogs. Concurrent dehydration often predisposes dogs to papillary necrosis. The mechanism of acute renal failure is related to the NSAIDs' decreasing synthesis of renal prostaglandins. Because prostaglandins are responsible for maintaining normal renal blood flow, NSAID administration results in afferent arteriolar constriction that decreases renal perfusion, resulting in acute tubular degeneration and necrosis and acute renal failure. The overall incidence of NSAID-induced renal failure in small animals is low and is seen most commonly in animals that ingest excessive amounts of the drug or have a concomitant disorder, such as dehydration, congestive heart failure, or chronic renal disease.

## Pathologic Basis of Veterinary Disease, 4th Edition

Naturally occurring nephrotoxins can originate from plants (ochratoxins and citrinins) or from fungal organisms (mycotoxins produced by *Aspergillus* sp. and *Penicillium* sp). Ochratoxin A is nephrotoxic for monogastric animals, particularly pigs, in which the lesions are tubular degeneration and necrosis. In addition, long-term ingestion results in diffuse renal fibrosis.

Nephrotoxic plant ingestion can result in acute tubular necrosis. Several species of pigweed, particularly *Amaranthus retroflexus*, can be responsible for acute tubular necrosis and perirenal edema in pigs and cattle. The toxic principle has not been identified. Ruminants develop tubular necrosis after ingestion of leaves, buds, or acorns from oak trees and shrubs (*Quercus* sp.). The toxic substances are metabolites of tannins; however, the mechanism of tubular damage is unknown. Acutely affected cattle often have swollen, pale kidneys that occasionally have cortical petechial hemorrhages (Fig. 11-42). Perirenal edema is a common lesion, and the body cavities contain excessive amounts of a clear fluid. The kidneys show acute tubular necrosis and in chronic cases are fibrotic, pale tan, reduced in size with thinned pale cortices, and have a finely pitted or dimpled surface.

655

656

**Fig. 11-42 Acute tubular necrosis, oak toxicity, kidney, cow.** Ingestion of leaves, buds, or acorns from oak trees produces cortical petechiation, acute tubular necrosis, and perirenal edema. The toxic principal is a metabolite of oak tannins and creates acute tubular necrosis, which heals by scarring. (Courtesy Dr. K. Read, College of Veterinary Medicine, Texas A&M University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Ethylene glycol (antifreeze) ingestion is a common cause of acute tubular necrosis in dogs and cats. Ethylene glycol, the major constituent of antifreeze, is readily absorbed from the gastrointestinal tract, and a small percentage is oxidized by hepatic alcohol dehydrogenase to the toxic metabolites glycolaldehyde, glycolic acid, glyoxylate, and oxalate. Ethylene glycol and its toxic metabolic products are filtered by the glomeruli, and acute tubular necrosis is caused by the direct interaction of these toxic metabolites, especially glycolic acid, with tubular epithelium (Fig. 11-43, A and B). Of particular significance is that calcium oxalate precipitates as large numbers of pale yellow crystals in renal tubular lumens, tubular epithelial cells, and the interstitium (Fig. 11-43, C). These crystals cause intrarenal obstruction and degeneration and necrosis of tubular epithelium subsequent to a postulated direct effect and/or mechanical damage. Using polarized light,

## Pathologic Basis of Veterinary Disease, 4th Edition

the microscopic identification of large numbers of these birefringent, round to pyramidal crystals arranged in rosettes or sheaves within renal tubules is virtually pathognomonic for ethylene glycol toxicity in dogs and cats (Fig. 11-43, *D*).

Oxalate-induced tubular necrosis also occurs in sheep and cattle after ingestion of toxic quantities of oxalates that accumulate in plants of various genera, such as *Halogeton*, *Sarcobatus*, *Rheum*, and *Rumex*. After absorption of these oxalates from the intestine, calcium oxalate deposits form and precipitate in vessel walls and in renal tubules, where they cause obstruction and epithelial cell necrosis. Illness in oxalate poisoning occurs not only because of renal disease but also because of neuromuscular dysfunction, the result of the hypocalcemia produced by chelation of serum calcium by oxalates. Recently, an oxalate-induced nephrosis was described in Tibetan spaniels with an inherited hyperoxaluria.

Vitamin D given as multiple excessive doses (vitamin D intoxication [vitamin D nephropathy]) or by accidental ingestion of calciferol-containing rodenticides can cause nephrosis in dogs and cats. In livestock, chronic ingestion of plants, such as *Cestrum diurnum* in the southern United States or *Solanum* sp. or *Trisetum* sp. in other countries, each of which contains a chemical with vitamin D–like biologic activity, can also cause nephrosis. Ingestion of excessive amounts of vitamin D can induce hypercalcemia. The subsequent tubular necrosis is the consequence of renal ischemia resulting from vasoconstriction and of tubular epithelial cell absorption of calcium, causing mitochondrial calcification, mitochondrial dysfunction, and cellular death. Tubular and glomerular basement membranes are also calcified (Fig. 11-29). Development of lesions depends on the length of time between exposure to rodenticides and death or the duration of continued exposure to vitamin D. In acute cases, the kidneys have a smooth capsular surface. Microscopically, tubular epithelium is necrotic and atrophic with a few calcific deposits in tubules scattered randomly throughout the cortex. In more chronic cases, the surface of the kidney is finely granular as a result of fibrosis. White, chalky calcific deposits can be seen within the cortex. Interstitial fibrosis, tubular dilation and atrophy, glomerular atrophy, and extensive calcification of tubular basement membranes are seen microscopically.

Natural gas condensate, a complex mixture of hydrocarbon compounds, has been reported to cause an acute nephrosis in exposed sheep. The mechanism of nephrotoxicity has not been identified, but it is not caused by heavy metal contaminants.

Bacterial toxins, such as the epsilon exotoxin, produced following notable enteric proliferation by *Clostridium perfringens* type D in small ruminants, can result in grossly recognizable bilateral renal lesions termed “pulpy kidney” (Fig. 11-44, *A*). The pulpy texture of the kidney is due to acute tubular epithelial degeneration and/or necrosis and interstitial edema and hemorrhage (Fig. 11-44, *B*).

### 11.2.3.4 INCIDENTAL LESIONS OF RENAL TUBULES

Pigment can be present in the renal tubules. The origin of hemosiderin pigment is most likely from degradation of hemoglobin resorbed from the glomerular filtrate by proximal tubular epithelium. However, a history of concurrent lesions of a prior hemolytic crisis are often lacking. In dogs, microscopic granules of hemosiderin are frequent incidental findings in the cytoplasm of proximal convoluted tubular epithelial cells in kidneys that are otherwise normal.

656

657

**Fig. 11-43 Oxalate nephrosis, kidney.** **A**, Pig. Oxalate nephrosis following ingestion of oxalate-containing plants. The kidney is diffusely pale beige and swollen. **B**, Dorsal section, dog. The cortex is pale beige and finely mottled due to the deposition of multiple small foci of oxalate crystals in the renal tubules. **C**, Dog. Tubular dilation, necrosis, and early regeneration (increased numbers of epithelial cells lining several tubules). Numerous tubules contain oxalate crystals (*arrows*) which have dilated the tubules and compressed their epithelium. H&E stain. **D**, Cat. Birefringent radiating sheaves of calcium oxalate crystals (*arrow*) in renal tubules. Polarized light. H&E stain. (**A**, **B**, and **D**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **C**, Courtesy Dr. S.J. Newman, College of Veterinary Medicine, University of Tennessee.)

Fine golden granules of lipofuscin (“wear and tear pigment”) can accumulate in renal proximal and distal convoluted tubules of old cattle and in striated muscle, resulting in lipofuscinosis. Grossly the renal cortex can have streaks of brown discoloration, but renal function is not affected.

Cloisonné kidneys, which occur in goats, are the result of tubular membrane thickening as a result of deposits of ferritin and hemosiderin. Grossly, these kidneys have diffuse, intense, black or brown discoloration of the cortex (Fig. 11-45). The medulla is spared. Although this lesion is striking, renal function is normal.

Other causes of incidental tubular changes include the following:

## Pathologic Basis of Veterinary Disease, 4th Edition

---

1. Vacuolation of renal tubular epithelium in the lysosomal storage diseases, such as feline sphingomyelinosis and ovine GM<sub>1</sub> gangliosidosis
2. Intranuclear eosinophilic crystalline pseudoinclusions (so called crystalloids), which occur in renal tubular epithelium of old dogs. These can be round or rectangular and often greatly distort the nuclei.

*Klossiella equi* is a sporozoan parasite of the horse, which has various stages of development in the kidney following oral infection. No gross lesions are noted. Various stages of schizogony can be found microscopically in proximal convoluted tubular epithelium and to a lesser extent in glomerular endothelium 657

---

(Fig. 11-46). Stages of sporogony are present in the epithelial cells of the loop of Henle, but different 658  
coccidial stages occur multifocally in affected tubules. Occasionally, however, *Klossiella equi* has been associated with multifocal lesions of mild tubular necrosis and with interstitial infiltrates of lymphocytes and plasma cells. Renal function is typically normal.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 11.2.3.5 TUBULOINTERSTITIAL NEPHRITIS

Bacterial infection of the pelvis with tubulointerstitial extension is referred to as pyelonephritis. Because of differences in pathogenesis, lesion distribution, and microscopic appearance, pyelonephritis is considered a separate entity from interstitial nephritis and is discussed later.

Fig. 11-45 **Cloisonné kidney, dorsal section, goat.** The cortex is diffusely black; the medulla is unaffected. (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

Fig. 11-46 ***Klossiella equi* infection, kidney, horse.** Tubular epithelium containing various developmental stages of *Klossiella equi* (arrows). H&E stain. (Courtesy Dr. J. Simon, College of Veterinary Medicine, University of Illinois.)

While interstitial inflammation, mounted against the veins, arteries, lymphatics, or connective tissues, appears to be the primary lesion, it has traditionally been called interstitial nephritis and may be of infectious or noninfectious cause and acute, subacute, or chronic in its duration. Interstitial nephritis is traditionally associated with a lymphoplasmacytic infiltrate; however, other types of leukocytes can also be present. In many of these diseases, the inflammatory cell infiltrates are visible only microscopically, are not associated with renal failure, and are generally inconsequential (examples are canine ehrlichiosis and equine infectious anemia). When the renal interstitium is the site of moderate to severe, grossly visible, interstitial inflammatory cell infiltrates and fibrosis, renal failure can occur.

658

659

More recently, the term *tubulointerstitial nephritis* has been used to characterize a group of inflammatory diseases that involve the interstitium and tubules. Acute tubulointerstitial disease includes a group of processes—namely, acute tubular necrosis, bilateral renal cortical necrosis, papillary necrosis, and acute interstitial nephritis. Tubulointerstitial nephritis can result from bacterial or viral septicemias, in which these infectious agents first infect the kidney tubules and then incite an inflammatory response in the interstitium (Table 11-4). Acute tubulointerstitial nephritis is characterized by the presence of inflammatory cells (principally neutrophils) within the interstitium and may result from toxicoses or from acute infection with agents such as leptospira (Fig. 11-47), adenoviruses, or herpesviruses. Chronic tubulointerstitial nephritis (Fig. 11-48, A) is a less well characterized entity in dogs, but atrophy of tubular segments is a significant feature of this syndrome along with sparse mononuclear cell infiltration, cortical and medullary fibrosis (Fig. 11-48, B), variable degrees of tubular and glomerular atrophy and/or sclerosis, and compromised nephron function. Three theories on the cause of chronic tubulointerstitial nephritis are: (1) focal acute interstitial nephritis evolves into the chronic form; (2) it is produced as a secondary manifestation of chronic glomerulonephritis (GN) or chronic pyelonephritis; or (3) it is produced following immune-mediated damage to the renal tubules and interstitium. There are few acute tubulointerstitial diseases to account for the large number of cases of chronic tubulointerstitial nephritis seen in dogs, and thus the first theory cannot account for a high percentage of the cases. As diagnostic techniques improve, some cases of chronic tubulointerstitial nephritis may be reclassified more specifically as either chronic pyelonephritis or secondary to chronic glomerulonephritis.

The pathogenesis of leptospirosis is discussed as an example of acute bacterial tubulointerstitial nephritis, the most well-understood causes of which include serovars of *Leptospira interrogans*:

1. Serovars *canicola* and *icterohaemorrhagiae* are the most common causes of canine leptospirosis.
2. Serovar *pomona* is the most common cause of the lesion in pigs and less consistently in cattle.
3. Other serovars, such as *grippityphosa* and *bratislava*, have also been associated with renal leptospirosis in several animal species.

Following exposure to the organism, leptospiremia occurs and then organisms:

1. Localize in the renal interstitial capillaries
2. Migrate through vascular endothelium
3. Persist in the interstitial spaces
4. Migrate via the lateral intercellular junctions of tubular epithelial cells to reach renal tubular lumina

## Pathologic Basis of Veterinary Disease, 4th Edition

5. Associate with epithelial microvilli
6. Persist within phagosomes of the epithelium of the proximal and distal convoluted tubules
7. Induce tubular epithelial cells to undergo degeneration and necrosis as a result of either direct toxic effects of the leptospire or the accompanying interstitial inflammatory reaction

### DOGS

*Leptospira interrogans* serovars *canicola*, *icterohaemorrhagiae*, and others

Infectious canine hepatitis virus, recovery phase

*Theileria parva*

Although neutrophils can be present in tubular lumina, the predominant chronic lesion is in the interstitium, which becomes infiltrated with monocytes, macrophages, lymphocytes, and plasma cells (Fig. 11-48, C and D). In affected dogs, interstitial plasma cells secrete *Leptospira*-specific antibodies. However, the role of those antibodies in pathogenesis or resolution of the lesion is not known.

Another well-documented mechanism for the production of tubulointerstitial nephritis is the immune response that develops secondary to canine adenoviral infection. The sequence of events includes the following:

1. Localization of virus in the glomeruli (viral glomerulitis) during the viremic phase of the disease (Fig. 11-49)
2. Production of a transient immune-complex glomerulonephritis

## Pathologic Basis of Veterinary Disease, 4th Edition

3. Recovery from the acute phase of the disease
4. Onset of the systemic immune response
5. Disappearance of virus from the glomeruli only to reappear in tubular epithelial cells in various portions of the nephron as basophilic intranuclear viral inclusions 659
6. Persistence of virus in tubular epithelium for weeks to months 660
7. Production of tubular epithelial necrosis as a result of viral-induced cytolysis
8. Production of chronic lymphocytic, plasmacytic, and less commonly histiocytic interstitial nephritis

**Fig. 11-47 Acute leptospirosis, kidney.** **A**, Interstitial nephritis, acute leptospira infection, dorsal section, dog. Radiating pale streaks are caused by cortical tubular necrosis, and acute interstitial inflammatory infiltrates. The hilar fat and medulla are yellow from jaundice. **B**, Acute tubular necrosis, early regeneration, dog. Note the segments of tubular epithelium devoid of nuclei (coagulation necrosis) (*top left*) and the hemorrhage. At this early stage, there is an almost complete lack of inflammatory cells in the interstitium, but later in the subacute stage of leptospirosis there are interstitial infiltrates of lymphocytes and plasma cells, which tend to be near the corticomedullary junction. H&E stain. **C**, Leptospira, cow. Numerous leptospira (*arrow*) are present in the lumens of tubules. Leptospira colonization of tubule epithelial cells is typical of this bacterium. Newman, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Infection with equine arteritis virus or porcine reproductive and respiratory syndrome virus often results in multifocal lymphohistiocytic chronic tubulointerstitial nephritis with interstitial edema. Lesions can involve any area of the cortex but are especially intense in the medulla and at the corticomedullary junction. A severe vasculitis, characterized by fibrinoid necrosis and lymphohistiocytic infiltrates that involve the adventitial and medial layers of cortical and medullary arteries and veins, is present. Virus can be found in endothelium and in macrophages.

Deposition of immune complexes in or interactions between antibasement membrane antibodies and tubular basement membranes can initiate immune-mediated tubulointerstitial disease in human beings and laboratory animals. Depositions of immunoglobulin (Ig) and complement have rarely been identified in renal tubular basement membranes in domestic animals, but administration of preformed complexes (bovine serum albumin and antibody) to dogs demonstrated that these complexes interacted with renal tubules, not glomeruli. Damaged tubules respond with epithelial cell and basement membrane proliferation and peritubular fibrosis. At present, the role of immune-mediated mechanisms in tubulointerstitial nephritis in domestic animals is unclear.

660

661

## Pathologic Basis of Veterinary Disease, 4th Edition

Gross lesions of tubulointerstitial nephritis can be classified as acute, subacute, or chronic; chronic tubulointerstitial nephritis is discussed in more detail later (see Renal Fibrosis). The distribution of lesions can be diffuse as in canine leptospirosis (Figs. 11-47 and 11-48) or multifocal as in “white spotted kidneys” of calves because of *Escherichia coli* septicemia (Fig. 11-50), infectious canine hepatitis, canine herpesvirus infection (Fig. 11-51), malignant catarrhal fever (Fig. 11-52), or porcine and bovine leptospirosis (Figs. 11-47 and 11-48). In diffuse tubulointerstitial nephritis, kidneys can be swollen and pale tan with a random gray mottling of the capsular surface. The cut surface bulges; gray infiltrates of varying sizes and intensities obscure the normal radially striated cortical architecture. These renal lesions usually are manifested as coalescing gray foci that are particularly intense in the inner cortex. Focal lesions of tubulointerstitial nephritis are less extensive and composed of more discrete gray areas in the cortex and outer medulla.

Microscopically, aggregates of lymphocytes, plasma cells, monocytes, and fewer neutrophils are randomly scattered or intensely localized throughout the edematous interstitium. Tubular epithelial cells within severely inflamed areas can be degenerate, necrotic, or both, and profound tubular loss is usually accompanied by eventual replacement fibrosis.

661

662

Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

11.2.3.6

### GRANULOMATOUS NEPHRITIS

Granulomatous nephritis is a tubulointerstitial disease that often accompanies chronic systemic diseases that are characterized by multiple granulomas in various organs. In domestic animals, granulomatous nephritis has been associated with a variety of infectious agents, including viruses (feline coronavirus), bacteria (mycobacteria), fungi (*Aspergillus* sp.), and parasites (*Toxocara* sp.). Common to each, however, is the

662

663

## Pathologic Basis of Veterinary Disease, 4th Edition

---

formation of grossly visible granulomas randomly scattered throughout the kidneys, but especially in the cortex.

**Fig. 11-50 Multifocal interstitial nephritis (white-spotted kidney), kidney, calf.** Multiple pale-yellow to white 2- to 5-mm foci of inflammatory cells (usually neutrophils) are scattered randomly throughout and over the surface of the kidney (as shown here). (Courtesy College of Veterinary Medicine, University of Illinois.)

Fig. 11-51 **Canine herpesvirus nephritis (canine herpesvirus type I), kidney, neonatal puppy.** **A**, Abdominal viscera. Multifocal renal cortical hemorrhages are grossly characteristic of this disease. **B**, Dorsal sections. Multifocal cortical hemorrhages are due to viral-induced vasculitis with necrosis and secondary hemorrhage. (**A** and **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 11-52 Interstitial nephritis, malignant catarrhal fever, kidney, dorsal section, gaur.** Multiple, pale-white to gray, discrete interstitial inflammatory cells (lymphoplasmacytic) have effaced some of the cortical striations in affected areas. (Courtesy Dr. A. Confer, College of Veterinary Medicine, Oklahoma State University.)

Cats with feline infectious peritonitis, particularly the noneffusive (dry) form, often have multifocal pyogranulomatous nephritis, secondary to the severe primary vasculitis. The pathogenesis of this lesion is thought to be related to a cell-mediated hypersensitivity (type IV) reaction to feline infectious peritonitis virus. The immune response causes a granulomatous necrotizing vasculitis and development of pyogranulomas. The renal lesions are characterized grossly by multiple, large, irregular, pale gray subcapsular cortical foci (Fig. 11-53, *A*) that are firm and granular on a cut surface (Fig. 11-53, *B*). These lesions are somewhat circumscribed and bulge from the capsular surface. They may be misinterpreted as neoplastic infiltrates, such as those associated with renal lymphosarcoma. Microscopically, extensive accumulations of macrophages interspersed with lymphocytes, plasma cells, and neutrophils (pyogranulomas) surround foci of necrotizing fibrinoid vasculitis (see Fig. 14-51).

Granulomatous nephritis is also caused by a variety of granuloma-inducing infectious agents including fungi such as *Aspergillus* sp., *Phycomycetes*, or *Histoplasma capsulatum*; algae such as *Prototheca* sp.; rickettsia such as *Ehrlichia canis*; protozoa such as *Encephalitozoon cuniculi*; and bacteria such as *Mycobacterium bovis*. Small, gray-white, granulomatous foci (2 to 5 mm) or larger nodules (up to 10 cm in diameter) can be scattered randomly throughout the kidneys of animals with granulomatous nephritis. These foci are white to tan, dry, and granular and can have calcified, caseous centers. Microscopically, lesions are characterized by central foci of necrosis surrounded by epithelioid macrophages, variable minerals, and giant cells that contain acid-fast bacteria.

In cattle, granulomatous nephritis is part of the multisystemic granulomatous disease caused by hairy vetch (*Vicia villosa*) toxicosis. Lesions are characterized by multifocal to coalescing cortical granulomas (Fig. 11-54, *A*). Microscopically, infiltrates of monocytes, lymphocytes, plasma cells, eosinophils, and multinucleated giant cells are seen primarily within the renal cortex (Fig. 11-54, *B*).

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Migratory *Toxocara canis* larvae can induce small, gray to white granulomas (2 to 3 mm) randomly scattered throughout the subcapsular renal cortex of dogs (Fig. 11-55, A). Such lesions probably are due to cell-mediated immune responses to the migrating larvae and are composed of aggregates of macrophages, lymphocytes, and eosinophils surrounded by fibroblasts within concentrically arranged fibrous connective tissue (Fig. 11-55, B). In recently acquired lesions, nematode larvae can often be seen in the center of these lesions (Fig. 11-55, B). Following death, the larvae become fragmented and the debris is either phagocytosed and eliminated or less commonly retained. Lesions heal by fibrosis, leaving a few finely pitted (contracted) foci on the capsular surface.

Fig. 11-53 **Granulomatous nephritis, feline infectious peritonitis, kidney, cat.** **A**, Lesions are typical of the noneffusive (dry) form of feline infectious peritonitis. There are multifocal, coalescing white to gray granulomas (*arrow*), which can be confused with the nodular form of lymphosarcoma, thus warranting histologic examination. **B**, Dorsal section. Multifocal, coalescing white to gray granulomas extend into the cortical parenchyma (*arrow*). The pathogenesis of this lesion is determined by the effectiveness and/or ineffectiveness of both humoral and cellular immune responses. Depending on the immune response, the pathogenesis can involve a primary immune complex vasculitis (type III hypersensitivity [effusive form]) and/or delayed hypersensitivity response (type IV hypersensitivity [noneffusive form]); thus the lesions are oriented around blood vessels (primarily capillaries and venules) and are granulomatous. (**A** and **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Cats with inherited hyperlipoproteinemia have xanthogranulomas in various organs, including the kidneys. 663

We have observed similar renal xanthogranulomas in dogs with hypothyroidism and severe atherosclerosis. 664

These lesions are characterized by foamy, lipid-laden macrophages, lymphocytes, plasma cells, and fibrosis interspersed with cleftlike spaces typical of cholesterol deposits (cholesterol clefts).

**Fig. 11-54 Granulomatous nephritis, hairy vetch toxicosis, kidney, cow.**

**A**, Cortical striations are obliterated by coalescing granulomatous foci associated with hairy vetch toxicosis. **B**, Cortex. Lesions associated with hairy vetch toxicosis are characterized by a mixed cell interstitial inflammatory infiltrate (macrophages, lymphocytes, and occasional multinucleated giant cell [arrow]) with renal tubular atrophy. It is specifically known as an unusual poisoning because of its ability to induce granulomatous inflammation in addition to the necrosis. The kidney is not the primary organ affected. H&E stain.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 11.2.4 DISEASES OF THE RENAL PELVIS

#### 11.2.4.1 PYELONEPHRITIS

Although *pyelitis* refers to inflammation of the renal pelvis, pyelonephritis is inflammation of both the renal pelvis and renal parenchyma and is an excellent example of suppurative tubulointerstitial disease. Each disease usually originates as an extension of a bacterial infection affecting the lower urinary tract that ascends the ureters to the kidneys and establishes an infection in the pelvis and inner medulla (Fig. 11-56). Rarely, pyelonephritis can result from descending bacterial infections, wherein bacterial infection of the kidneys occurs via the hematogenous route, that is, embolic nephritis. In human pathology, the term *pyelonephritis* is used to include both ascending and descending infections (Fig. 11-57). Ascending infection, however, is by far the most common cause of pyelonephritis in animals.

**Fig. 11-55 Granulomatous nephritis, kidney, cortex, dog.** **A**, Multiple subcapsular, cortical, tan, raised granulomas caused by migrating ascarid larvae. **B**, A mature granuloma composed of a central ascarid larva surrounded by epithelioid macrophages and concentrically arranged fibrous connective tissue and inflammatory cells. H&E stain. *Inset*: Ascarid larva. (**A**, **B**, and *Inset*, Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

The pathogenesis of ascending pyelonephritis depends on the abnormal reflux of bacteria-contaminated urine from the lower tract to the renal pelvis and collecting ducts (vesicoureteral reflux). Normally, little vesicoureteral reflux occurs during micturition. Vesicoureteral reflux occurs more readily when pressure is increased within the urinary bladder, as with urethral obstruction. Bacterial infection of the lower urinary tract can enhance vesicoureteral reflux by several other mechanisms:

664

665

1. When the bladder wall is inflamed (cystitis), the normal competency of the vesicoureteral valve can be compromised, allowing greater opportunity for urine to reflux.
2. Endotoxin, liberated from gram-negative bacteria infecting the ureter and bladder, can inhibit normal ureteral peristalsis, increasing reflux.

**Fig. 11-56 Schematic diagram of the pathways of renal infection.**

Hematogenous infection results from bacteremia. More common is ascending infection, which results from a combination of urinary bladder infection, vesicoureteral reflux, and intrarenal reflux. (From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

**Fig. 11-57 Schematic diagram of pyelonephritis, kidney, human being.**  
Typical coarse scars of chronic pyelonephritis associated with vesicoureteral reflux. The scars are usually polar and with the loss of the renal papilla, the calyx underlying each scar is blunted. The cow and pig are the only domestic animals with calyces. (From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

The urinary tract has a number of protective features in place to help prevent bacterial colonization and these include the following:

1. Mucoproteins in the surface urothelial mucosal lining that prohibit bacterial adherence
2. Desquamation of superficial urothelial cells to minimize surface colonization
3. Goblet cell metaplasia
4. Phagocytosis by superficial mucosal urothelial cells

Bacteria that colonize the pelvis can readily infect the inner medulla. The medulla is highly susceptible to bacterial infection because of the following:

1. Its poor blood supply
2. Its great interstitial osmolality or osmolarity that inhibits neutrophil function

### 3. Its large ammonia concentration that inhibits complement activation

Thus bacteria can infect and ascend collecting ducts, cause tubular epithelial necrosis and hemorrhage, and incite a notable inflammatory response. Bacterial infection can progressively ascend within tubules and the interstitium until the inflammatory lesions extend from pelvis to capsule. Chronic pyelonephritis may result from infection superimposed on conditions that result in recurrent obstructive disease or reflux (reflux nephropathy). Recurrent infections lead to recurrent bouts of inflammation that result in scarring.

665

Because most occurrences of pyelonephritis are ascending infections and because females are more susceptible to lower urinary tract infections, pyelonephritis occurs more frequently in females. *Escherichia coli*, especially uropathogenic strains that produce virulence factors such as  $\alpha$ -hemolysin, adhesions, and P fimbria, is one of the most common causes of lower urinary tract disease and pyelonephritis. *Proteus* sp., *Klebsiella* sp., *Staphylococcus* sp., *Streptococcus* sp., and *Pseudomonas aeruginosa* are also common causes of lower urinary tract infection and pyelonephritis in all species. *Corynebacterium renale* and *Eubacterium* (*Corynebacterium*) *suis* are specifically pathogenic for the lower urinary tract of cattle and pigs, respectively, and are common causes of pyelonephritis. Recent or multiple catheterizations may be a predisposing factor.

666

A gross diagnosis of pyelonephritis is accomplished by recognizing the existence of pelvic inflammation with extension into the renal parenchyma (Fig. 11-58, A). Pyelonephritis can be unilateral, but it is often bilateral and most severe at the renal poles. The pelvic and ureteral mucous membranes can be acutely inflamed, thickened, reddened, roughened or granular, and coated with a thin exudate. The pelvis and ureters can be markedly dilated and have purulent exudate in the lumina (Fig. 11-58, B). The medullary crest (papilla) is often ulcerated and necrotic. Renal involvement is notable by irregular, radially oriented, red or gray streaks involving the medulla, extending toward and often reaching the renal surface (Fig. 11-58). Occasionally, inflammation extends through the surface of the kidneys to produce extensive subcapsular inflammation and localized peritonitis.

**Fig. 11-58 Pyelonephritis, kidney.** **A**, Dorsal section, dog. Extensive pelvic inflammation has destroyed areas of the inner medulla and extends focally into the outer medulla. **B**, Dorsal section, cow. Renal calyces in the cow contain suppurative exudate. **C**, Dog. There is both intratubular and interstitial inflammation, characterized by infiltrates of principally neutrophils (*arrow*). *Inset*: Higher magnification of intratubular neutrophils. H&E stain. (**A**, **C**, and ***Inset***, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy Dr. K. Read, College of Veterinary Medicine, Texas A&M University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

The renal lesions of chronic pyelonephritis, in which an active bacterial infection exists, include most of the elements of acute inflammation described previously and extensive necrosis of the medulla, patchy fibrosis in the outer medulla and cortex, and variable amounts of pelvic inflammatory exudates. Chronic pyelonephritis often produces a grossly visible deformity of the renal parenchyma because of extensive interstitial inflammation and scarring (Fig. 11-58).

666

667

Microscopically the most severe acute lesions of pyelonephritis are usually in the inner medulla. The transitional epithelium is usually focally or diffusely necrotic and desquamated. Necrotic debris, fibrin, neutrophils, and bacterial colonies can be adherent to the denuded surface. Medullary tubules are notably dilated, and their lumina contain neutrophils and bacterial colonies. Focally the tubular epithelium is necrotic. An intense neutrophilic infiltrate, present in the renal interstitium, can be accompanied by notable

## Pathologic Basis of Veterinary Disease, 4th Edition

---

interstitial hemorrhages and edema (Fig. 11-58, C). If obstruction of vasa recta has occurred, coagulative necrosis of the inner medulla (papillary necrosis) can be severe. Similar tubular and interstitial lesions, although less severe, extend radially into the cortical tubules and interstitium. When the lesions become subacute, the severity of the neutrophilic infiltrates diminishes, and lymphocytes, plasma cells, and monocytes infiltrate the interstitium. Chronic lesions have severe fibrosis. If active bacterial infection persists or is untreated, an intense infiltrate of all inflammatory cell types interspersed with tubular necrosis and fibrosis can be seen. All stages of disease progression can occur in a single kidney.

11.2.4.2

### HYDRONEPHROSIS

*Hydronephrosis* refers to dilation of the renal pelvis because of obstruction of urine outflow and is principally caused by a slow or intermittent increase in pelvic pressure. Abrupt increases in pressure, such as those associated with inadvertent surgical ligation of a ureter, more commonly result in a decline in filtration rate in the affected kidney and a lesser propensity to develop hydronephrosis.

Obstruction leading to hydronephrosis can occasionally be caused by congenital malformation of the ureter, vesicoureteral junction, or urethra or from congenitally malpositioned kidneys with secondary kinking of the ureter. The more common causes of hydronephrosis are as follows:

1. Ureteral or urethral blockage due to urinary tract calculi (see Lower Urinary Tract)
2. Chronic inflammation
3. Ureteral or urethral neoplasia
4. Neurogenic functional disorders

Hydronephrosis occurs in all domestic animals. Depending on the location of the obstruction, hydronephrosis can be unilateral (ureteral) or bilateral (both ureters, bladder trigone, or urethra). Unilateral hydronephrosis is caused by obstruction of the ureters anywhere throughout its length or at its entrance into the urinary bladder. Bilateral hydronephrosis can be caused by urethral obstruction, bilateral ureteral obstruction, or extensive urinary bladder lesions centered on the trigone. When hydronephrosis is unilateral, pelvic enlargement of the kidney can become extensive, even cystic, before the lesion is recognized clinically. If the obstructive process causes partial or intermittent blockage, bilateral hydronephrosis can become notable because of continual urine production and pooling of urine in the expanding pelvis. When obstruction is complete and bilateral, death as a result of uremia occurs before pelvic enlargement becomes extensive.

When the increase in intrapelvic pressure is substantial and sustained, the following occur:

1. Intratubular pressure is increased and results in microscopic renal tubular dilation.
2. Glomeruli remain functional, and even with complete obstruction, glomerular filtration does not stop completely and soon overwhelms tubular reabsorption pathways.
3. Much of the glomerular filtrate diffuses into the interstitium, where it is initially removed via lymphatic vessels and veins.
4. As intrapelvic pressure increases, the interstitial vessels collapse and renal blood flow is reduced, resulting in hypoxia, tubular atrophy, and, if the pressure increase is continued, interstitial fibrosis.

## Pathologic Basis of Veterinary Disease, 4th Edition

5. The glomeruli have a relatively normal morphologic appearance for a prolonged period, but they eventually become atrophic and sclerotic.

Early changes of hydronephrosis include dilation of the pelvis and calyces and blunting of the renal crest and papillae (Fig. 11-59). When pelvic dilation is progressive, the kidney silhouette is enlarged and rounder than normal, and the cortex and medulla are progressively thinned (Fig. 11-60). Interstitial vascular obstruction from compression produces an expanding front of medullary and later cortical ischemia and necrosis. The continued pelvic dilation causes loss of tubules by degeneration and atrophy, followed by condensation of interstitial connective tissue and fibrosis of the renal parenchyma. In its most advanced form, the hydronephrotic kidney is a thin-walled (2- to 3-mm-thick), fluid-filled sac. This sac is lined by flattened transitional epithelium, which is spared during lesion development. Occasionally, a severely hydronephrotic kidney becomes contaminated by bacteria and the thin-walled sac becomes filled with pus instead of urine. This lesion, referred to as pyonephrosis, is likely the result of blood-borne bacteria lodging in a hydronephrotic kidney.

667

668

**Fig. 11-59 Hydronephrosis, kidney, dorsal section. A, Sheep.** The pelvis of each kidney is markedly dilated. **B, Cow.** Bovine kidneys are lobulated, and each lobule has its own renal papilla surrounded by a calyx, an extension of the pelvis. Thus in early hydronephrosis, each of these calyces is distended, and these distended calyces should not be confused with the cysts of a cystic or polycystic kidney. (**A**, Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University. **B**, Courtesy College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 11.2.4.3 PARASITES

The giant kidney worm (*Diectophyma renale*) is seen infrequently in dogs from temperate and cold countries worldwide. It is endemic in Canada and in northern regions of the United States. Because of a prolonged and complex life cycle, this nematode is seen only in dogs 2 years old or older. The adult nematode is red and cylindrical, with the females measuring 20 to 100 cm long and 4 to 12 mm in diameter, and the males measuring 14 to 45 cm long and 4 to 6 mm in diameter. This nematode resides in the renal pelvis where it causes severe hemorrhagic or purulent pyelitis, subsequent ureteral obstruction, and destruction of the renal parenchyma, resulting in a hydronephrotic kidney that appears as a cyst containing the nematode and purulent exudate.

In North America, the kidney worm (*Stephanurus dentatus*) is found most often in adult pigs in southern regions of the United States. The parasite is also a problem in other countries with warm climates. Adult worms normally encyst in perirenal fat; however, some parasites may reside in the kidney. Peripelvic cysts often communicate with the renal pelvis and ureter, and fibrosis and chronic granulation tissue can enclose the parasite. Occasionally, nematode eggs are present in the urine sediment.

**Fig. 11-60 Chronic hydronephrosis, kidney, dorsal section, cat.** Advanced hydronephrosis is characterized by loss of medullary tissue and atrophy or even loss of the entire cortex in response to elevated pelvic fluid pressure. Note that this case was so severe that only the renal capsule, which contains clear yellow fluid, remains. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

*Capillaria plica* and *Capillaria feliscati* have been identified infrequently in dogs and cats worldwide. Typically, these nematodes are attached to the renal pelvis, ureter, or bladder of animals of various ages. Microscopically, inflammatory cells infiltrate and focal hemorrhages are associated with sites of attachment in the underlying submucosa. Clinical effects usually are not present, but hematuria and dysuria are produced occasionally.

### 11.2.5 RENAL FIBROSIS (SCARRING)

Renal fibrosis is the replacement of renal parenchyma, including tubules, glomeruli, and interstitium with mature fibrous connective tissue (Fig. 11-61). It can occur as a primary event, but more frequently is a manifestation of the healing phase of a preexisting tubular or glomerular lesion. It is the common end point of all reparative stages and results when conditions are not conducive for healing of the tubular epithelium by regeneration. Regeneration of nephrons as a whole is not possible. Renal fibrosis follows many renal lesions, including primary inflammation of glomeruli (glomerulonephritis), tubules, or interstitial tissue (tubulointerstitial nephritis) and necrosis of renal tubules. Its severity usually parallels the intensity of the primary renal disease. The mechanisms by which fibrosis is induced are related to destruction and loss of nephron components by inflammatory or less commonly noninflammatory processes. Renal fibrosis is seen commonly following any number of renal insults and includes the following:

668

669

1. Infarction
2. Glomerulonephritis/amyloidosis
3. Tubulointerstitial disease/chronic pelvic diseases

Fig. 11-61 **Chronic interstitial nephritis, kidney, dog.** **A**, Diffuse interstitial fibrosis is responsible for the fine pitting of the capsular cortical surface, which is stippled red, the result of bands of fibrous tissue (*gray*) surrounding islands of renal cortex. **B**, Dorsal section. The cortex is pitted and granular because of multiple linear and focal scars, and it is also thinner than normal (atrophic). (**A** and **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Without careful attention to the pattern of resultant fibrosis, such kidneys can be indiscriminately termed as end-stage kidneys; however, fibrosis generally follows a pattern characteristic of the antecedent injury and will be described next for glomerular disease, renal tubular necrosis, and tubulointerstitial disease.

The distribution of fibrosis secondary to glomerular disease is diffuse and primarily cortical. This is because most primary glomerular diseases involve all glomeruli throughout the renal cortex and ultimately result in glomerulosclerosis of some significance. Additionally, because the blood flow through glomerular capillaries is reduced in chronic glomerulonephritis and amyloidosis, the pattern of interstitial fibrosis is diffuse. Sustained proteinuria can also increase tubular epithelial cell apoptosis, leading to tubular atrophy and interstitial fibrosis. Because all components of the nephron are interdependent, glomerular fibrosis and loss of function ultimately results in secondary atrophy of cortical and medullary tubules and fibrosis of the cortical and to a lesser degree medullary interstitium.

Diffuse fibrosis with a finely granular pattern can occur subsequent to widespread necrosis of renal tubular epithelium (acute tubular necrosis). An example is oak poisoning of cattle (Fig. 11-42), in which severe tubular necrosis extends to the level of the renal tubular basement membrane, resulting in leakage of tubular contents. The loss of the continuity of the basement membrane prevents orderly tubular epithelial cell regeneration and this can be followed by interstitial fibrosis. Recent experimental studies have demonstrated that after severe nephrotoxin-induced tubular epithelial cell injury, the remaining cells undergo accelerated apoptosis resulting in tubular atrophy, interstitial fibroblast proliferation, and eventual fibrosis.

Different coarser patterns of renal fibrosis occur when the primary lesion is less evenly distributed in the kidneys. Fibrosis secondary to the tubulointerstitial inflammation of pyelonephritis follows the pattern of the acute disease (targeting the renal poles), and results in irregularly distributed, patchy scarring that is seen as deeply depressed regions on the renal capsular surface and linear areas extending through both the cortex and medulla to the pelvis (Fig. 11-62).

The scarring that follows embolic or thrombotic vascular obstruction and infarction is related to several variables, including the size of the ischemic area caused by vascular compromise. Ischemia resulting from obstruction of relatively large arterioles causes large areas of coagulative necrosis. Healing results in large, deeply depressed wedge-shaped scars that involve primarily the cortex, but can extend into the medulla. Obstruction of smaller arterioles results in smaller areas of more superficial coagulative necrosis that heal as small-diameter pits in the renal surface, which correspond to pale white, linear scars on the cut surface.

A coarser pattern of diffuse renal fibrosis occurs in chronic interstitial nephritis and certain progressive juvenile nephropathies of dogs. Both cortex and medulla can be fibrotic; cortical striations are severely distorted or effaced; and the formation of multiple cortical cysts is common.

669

670

Fig. 11-62 **Chronic pyelonephritis, kidney, dog.** **A**, Note the two large polar scars visible as large indentations on the capsular surface (*arrow*). The fine gray spots are regions of chronic inflammatory infiltrates and fibrosis. **B**, Dorsal section. The cortical scars are localized to the renal poles (*arrow*), but there is a finely stippled pattern of nodularity and fibrosis in the remaining kidney. This polar pattern of scarring suggests previous pyelonephritis. (**A** and **B**, Courtesy Dr. A. Confer, College of Veterinary Medicine, Oklahoma State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Specifically, renal fibrosis may manifest in a multitude of grossly recognizable forms as described previously. Generally, fibrotic kidneys are recognized grossly by the pale, tan-to-white, shrunken, pitted and firm consistency along with excessive adhesions of the capsule to the underlying cortex. Fibrosis can be diffuse and finely stippled with pinpoint dimpling and granularity on the capsular surface, or it can be coarser as seen by deep and irregularly shaped depressions of the capsular surface in either a diffuse, multifocal, or patchy distribution. In addition to these changes of the capsular surface, the cut surface of the cortex is thinned beneath the capsular surface depressions, and these fibrotic areas are pale tan when compared with more normal parenchyma.

Microscopically, renal fibrosis is characterized by an increase in interstitial connective tissue and disappearance of renal tubules (Fig. 11-63, A). Remaining tubules are usually atrophic and have a reduced luminal diameter or can appear ectatic because they are lined by flattened epithelium, producing an enlarged luminal diameter. A thickened hyalinized basement membrane and a lining of flattened epithelium (squamous or low cuboidal) are also characteristic. Multiple acquired cysts can be present throughout the cortex and medulla and can be a result of either dilated Bowman's capsules and associated atrophic glomerular tufts or nephrons whose tubules have segments compressed by connective tissue (Fig. 11-63, B). Even in fibrotic lesions that are not the result of an infectious disease or inflammation, foci of lymphocytes and plasma cells can be seen randomly scattered throughout the interstitium (Fig. 11-63, C). In areas of severe interstitial fibrosis, glomerulosclerosis (as an end stage of isolated glomeruli) is common. Calcification of vessels, tubular basement membranes, Bowman's capsules, and degenerate tubular epithelium is common in fibrotic kidneys because of alterations in calcium-phosphorus metabolism associated with chronic renal failure (Fig. 11-29).

Renal fibrosis and chronic renal disease are the most frequently recognized renal pathologic processes in mature or aging domestic animals, particularly dogs and cats. When renal fibrosis and loss of nephrons are severe, these lesions can be manifested clinically as chronic renal failure and uremia. One of the most common expressions of this chronic disease is the inability of an animal to concentrate urine, resulting in frequent urination (polyuria) of dilute urine (isosthenuria). Polyuria is accompanied by dehydration and excessive water drinking (polydipsia). Hypoplastic anemia occurs as a result of the kidneys' failure to synthesize and secrete erythropoietin. Fibrous osteodystrophy can develop because of abnormal calcium-phosphorus metabolism and renal secondary hyperparathyroidism.

### 11.2.5.1 Progressive Juvenile Nephropathy

The development of severe bilateral renal fibrosis has been described in young dogs of several breeds and referred to as progressive juvenile nephropathy or familial (hereditary) renal disease (Table 11-5). In many dogs, a familial tendency is demonstrated, but the mode of inheritance has been determined with certainty in only a few dog breeds. In Samoyeds, the lesion is sex-linked; in bull terriers, it is autosomal dominant; and in the Shih Tzu, the disease appears to have a simple autosomal recessive inheritance. Recently, a progressive juvenile nephropathy, similar to that seen in dogs, was described in six young Japanese black cattle. The cattle had a common male ancestor, suggesting a familial basis.

670

671

**Fig. 11-63 Chronic interstitial nephritis, kidney, dog.** **A**, Dorsal section, cortex. This lesion is characterized by interstitial fibrosis, tubular atrophy, and interstitial inflammatory cell (lymphocytes and plasma cell) infiltration. Note the depressed capsular surface as a result of scarring and the shrunken sclerotic glomeruli (*arrow*). H&E stain. **B**, Acquired cystic tubules are due to constriction of portions of the nephron by renal fibrosis. H&E stain. **C**, Cortex. Higher magnification of notable interstitial fibrosis, lymphocytic inflammatory infiltrates, sclerotic glomerular tufts, and ectatic tubules and Bowman's spaces. H&E stain. (**A** and **C**, Courtesy Dr. S.J. Newman, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Progressive juvenile nephropathy is a syndrome, the morphologic manifestations of which can be the result of any of several chronic pathologic processes. The main manifestations include the following:

1. Membranoproliferative glomerulonephritis
2. Tubular disease of unknown cause with tubular atrophy and interstitial fibrosis
3. Renal dysplasia

## Pathologic Basis of Veterinary Disease, 4th Edition

Gross renal lesions of progressive juvenile nephropathy are variable among affected breeds and among affected dogs within a breed. Generally, kidneys are notably shrunken, pale tan to white, and firm (Fig. 11-11, C and D). The renal surface can be diffusely pitted and have a fine granular pattern, particularly in those dogs in which glomerular disease is the primary event. In these cases of juvenile nephropathy that are of tubular origin or dysplastic, the renal surface can have patchy, deeply depressed areas of cortical scarring. On the cut surface, the cortex is thin and has linear radial scars. The medulla is usually diffusely fibrotic. Small (1 to 2 mm), variably sized cysts are seen often in the cortex and the medulla.

671

672

Table 11-5 Breeds of Dogs with Progressive Juvenile Nephropathy

American cocker spaniels
English cocker spaniels
Norwegian elkhounds
Samoyeds
Doberman pinschers
Lhasa apsos
Shih Tzus
Soft-coated Wheaten terriers
Bull terriers
Standard poodles
Alaskan malamutes
Miniature schnauzers
German shepherds
Keeshonds
Chow chows
Weimaraners
Golden retrievers

In the Doberman pinscher, the primary lesion is a glomerulopathy that appears microscopically as a membranoproliferative glomerulonephritis. Later in the clinical course of the disease, the lesions include extensive periglomerular fibrosis, tubular atrophy, and cystic dilation of Bowman's (urinary) space and tubules. In affected Samoyeds and English cocker spaniels, multilamellar splitting of the glomerular basement membrane is caused by inherited abnormalities in basement membrane collagen. These lesions progress to severe glomerulosclerosis.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

In Norwegian elkhounds, a tubular disorder of unknown cause has been described and is characterized by progressive tubular atrophy, periglomerular and interstitial fibrosis, and glomerulosclerosis without any indication of a primary glomerular disease.

Progressive juvenile nephropathy has been described in Lhasa apsos, Shih Tzus, Wheaten terriers, standard poodles, and golden retrievers as a condition resembling renal dysplasia, defined as an abnormality of renal development as a result of anomalous differentiation. Small, shrunken, fetal-like glomeruli composed of small cells with dense nuclei, minimal mesangial tissue, and nonpatent capillaries can be seen interspersed with normal, sclerotic, or hypertrophied glomeruli. Other lesions include marked interstitial fibrosis and tubular dilation. Most of the kidneys have minimal lymphoplasmacellular interstitial cell infiltrates.

Although variations exist in gross and microscopic lesions (Fig. 11-11, *E*), as well as in the pathogenesis of progressive nephropathy among the different breeds, a typical case is a dog 4 months to 2 years of age that has polyuria, polydipsia, and uremia. The clinical presentation, gross lesions, and microscopic changes are identical to those of chronic renal disease and renal fibrosis in mature or aging dogs.

### 11.2.6 CIRCULATORY DISTURBANCES

#### 11.2.6.1 HYPEREMIA AND CONGESTION

*Hyperemia* refers to an increase in arterial blood flow, and *congestion* is an increase in venous blood pooling within the vasculature of the kidney. Renal hyperemia is an active process usually secondary to acute renal inflammation. Renal congestion can be:

1. Physiologic
2. Passive
3. Secondary to hypovolemic shock
4. Secondary to cardiac insufficiency
5. Hypostatic

Hyperemic kidneys are darker red than normal, can be perceptibly swollen, and ooze blood from the cut surface. Congested kidneys are dark purple and ooze blood from the cut surface due to the accumulation of unoxygenated blood in the renal venous system. At necropsy, unilateral renal hypostatic congestion is present in animals that die in lateral recumbency, following which the force of gravity pulls the unclotted blood downward. Microscopically the arterial and venous vessels are distended with blood, and if there has been sufficient time for the blood to clot, serum and blood cells may be present.

#### 11.2.6.2 HEMORRHAGE AND THROMBOSIS

Hemorrhage occurs when red blood cells extend beyond the vessel walls. Large intrarenal hemorrhages can result from direct trauma, renal biopsy, and systemic bleeding disorders, such as factor VIII deficiency. Subcapsular and renal cortical hemorrhages occur in association with septicemic diseases, vasculitis, vascular necrosis, thromboembolism, and disseminated intravascular coagulation (DIC).

## Pathologic Basis of Veterinary Disease, 4th Edition

Petechial hemorrhages are commonly seen on the surface and throughout the cortex of kidneys from pigs that die of viremia or septicemia caused by diseases such as hog cholera (swine fever), African swine fever, erysipelas, streptococcal infections, salmonellosis, and other embolic bacterial diseases (Fig. 11-64). Renal cortical ecchymotic hemorrhages associated with multifocal tubular and vascular necrosis are salient and diagnostically important lesions of viremia in neonatal puppies infected with herpesvirus. Valvular endocarditis can predispose to renal thromboembolic damage in any species.

When DIC causes widespread thrombosis in the glomerular capillaries (Fig. 11-65), the interlobular arteries, and afferent arterioles, widespread cortical infarction results and is designated renal cortical necrosis. This lesion is not to be confused with ischemic acute tubular necrosis discussed in this chapter (see Tubular Necrosis). Partial or complete renal cortical necrosis is usually a bilateral lesion that occurs in all animal species, especially in association with gram-negative septicemias or endotoxemias, and is related to the following:

672

673

1. Endotoxin-induced endothelial damage
2. Activation of the extrinsic clotting mechanism
3. Widespread capillary thrombosis

**Fig. 11-64 Bacterial-induced septicemic renal cortical hemorrhages, erysipelas, kidney, pig.** **A**, Petechial hemorrhages caused by septic emboli of *Erysipelothrix rhusiopathiae* are randomly scattered over the capsular surface of the kidney. **B**, Dorsal section. Similar petechiae are present on the cut surface of the renal cortex. (**A** and **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

The lesion can be induced experimentally in animals by two endotoxin injections 24 hours apart and is a manifestation of the generalized Shwartzman reaction.

The resulting microthrombosis of vessels throughout the renal cortex results in widespread ischemia and small and large areas of coagulation necrosis and hemorrhage. The renal cortex can be diffusely pale with a zone of hyperemia separating the necrotic cortex from the viable medulla, or more often the cortex is a mosaic of large, irregular hemorrhagic areas, resembling hemorrhagic infarcts interspersed with large yellow-gray areas resembling pale infarcts. The necrotic tissue can involve the full width of the cortex or only the outer portion. Thrombi are demonstrable in the renal vasculature.

**Fig. 11-65 Glomerular capillary thrombosis, kidney, glomerulus, dog. A,** Microthrombi. Capillary lumens are occluded by microthrombi (*arrows*) caused by disseminated intravascular coagulation. Adjacent cortical tubular epithelial cells are undergoing coagulation necrosis with nuclei undergoing pyknosis and karyolysis (*arrowhead*), the result of ischemia from reduced blood flow to the peritubular capillaries, which are downstream from the glomerulus. H&E stain. **B,** Fibrinous microthrombi. A glomerulus similar to the one shown in [Fig. 11-65, A](#) stained to demonstrate fibrinous thrombi (*arrows*). Fibrin is red. Lendrum-Fraser stain for fibrin. (**A**, Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy College of Veterinary Medicine, University of Illinois.)

Renal infarcts are areas of coagulative necrosis that result from the local ischemia of vascular occlusion and usually are due to thromboembolism secondary to valvular endocarditis; endarteritis from parasitic diseases, such as heart worm or strongyles; mural thrombosis (atherosclerotic plaque); or aseptic emboli (neoplastic emboli).

673

Because of the high circulating blood volume (20% to 25 % of cardiac output) through the kidney, renal infarcts from thromboemboli secondary to embolism from mitral or aortic valvular vegetative endocarditis or mural endocarditis are common in many species, especially in cats with left atrial thrombosis associated with cardiomyopathy. Rarely, emboli may occlude the renal artery, causing infarction of the entire kidney. Sometimes emboli occlude the interlobar arteries, causing infarction of variable segments of the cortex and medulla. Most commonly, emboli obstruct many smaller vessels (e.g., interlobular arteries), causing multiple smaller infarcts involving only the renal cortex. In general, renal infarction can occur because of thrombosis resulting from endothelial damage associated with a vascular disease (as in Alabama rot in greyhounds; [Fig. 11-25](#)) or with cardiovascular collapse and shock. Renal infarcts in horses can result from emboli lodging in the renal vasculature following mural thrombosis of the aorta, from aortic wall damage, and from migrating larvae of *Strongylus vulgaris*. Thrombosis of pulmonary, coronary, splenic, or renal arteries and resultant infarction are common in dogs with renal amyloidosis primarily because of loss of plasma anticoagulants, such as antithrombin III, through damaged glomeruli. Endotoxin-mediated arterial or capillary thrombosis is a common cause of infarction in association with gram-negative sepsis or endotoxic shock. Septic emboli, particularly those from bacterial valvular endocarditis, caused by *Arcanobacterium pyogenes* in cattle, *Erysipelothrix rhusiopathiae* in pigs, and *Staphylococcus aureus* in small animals can cause renal infarcts.

674

Grossly, renal infarcts appear red or pale white depending on several factors, including the interval after vascular occlusion (i.e., age of infarct) ([Figs. 11-66](#) and [11-67](#)). Occlusion of small interlobular arteries results in infarcts that are initially slightly swollen and red because of hemorrhage ([Fig. 11-67, A](#)) and which later become pale yellow-gray within 2 to 3 days because of lysis of erythrocytes and loss of hemoglobin ([Fig. 11-67, B](#)). Initially, large infarcts develop when an embolus lodges in the interlobular artery closer to its origin from the arcuate artery. These larger infarcts have a central area of pallor (coagulative necrosis) and are usually surrounded by a peripheral red zone of congestion and hemorrhage along with a pale margin because of a surrounding zone of leukocytes ([Fig. 11-67, C](#)). Because of the loss of parenchyma, healing infarcts are depressed below the cortical surface, and later become pale and shrunken as a result of fibrosis ([Fig. 11-67, D](#)).

Fig. 11-66 **Schematic diagram of renal infarction.** The normal progression of renal infarcts is outlined. **A** and **B**, Acute renal infarcts. Initially, renal infarcts are swollen and hemorrhagic (**A**). In 2 to 3 days, infarcts become pale (**B**), surrounded by a zone of hyperemia and hemorrhage. **C**, Chronic infarcts are pale, shrunken, and fibrotic, resulting in distortion and depression of the renal contour. See Fig. 11-1 for identification of the anatomic components of the kidney.

Infarcts are often wedge-shaped in a cross section of kidney, with the base against the cortical surface and the apex pointing toward the medulla, conforming to a zone of cortical parenchyma supplied by the obstructed interlobular artery. Infarcts can involve the cortex only or the cortex and medulla depending on the size of the occluded vessel and the site of obstruction. For example, thrombosis of an arcuate artery, which supplies both cortex and medulla, would result in an infarct involving the cortex and extending partway into the medulla (Fig. 11-4). Thrombosis of a cortical interlobular artery, which supplies mainly the cortex, would result in an infarct of the cortex only (Fig. 11-4). Although less common, hypoxic renal necrosis due to venous occlusion and/or infarction are seen occasionally, and they retain their hemorrhagic appearance longer than infarcts resulting from arterial occlusion because of the continued arterial blood flow into the area.

674

**Fig. 11-67 Gross appearance of renal cortical infarcts with age, kidney, dorsal sections. A,** Acute (early) hemorrhagic infarct, dog. Focal wedge-shaped area of cortical necrosis. Note how the infarct bulges above the capsular surface due to cell swelling and hemorrhage. **B,** Acute pale infarcts, rabbit. There are two pale white to tan wedge-shaped infarcts (*top, lower right*). Note how the infarct (*top*) bulges above the capsular surface, indicating cell swelling. **C,** Subacute infarcts, dog. Multiple renal cortical infarcts are pale and surrounded by a red rim of active hyperemia. The cortical surface of many, but not all, of the infarcts is even with that of the adjacent unaffected cortex, indicating that cell swelling has subsided. **D,** Chronic infarct, cat. A focal pale truncated wedge-shaped scar of fibrous connective tissue has replaced the pole of the renal cortex. Note that the surface of the infarct is below that of the adjacent normal kidney because of the loss of tissue, fibrosis, and contraction of the fibrous scar. (**A,** Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B,** Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **C,** Courtesy Dr. K. Read, College of Veterinary Medicine, Texas A&M University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **D,** Courtesy Dr. J. Sagartz, College of Veterinary Medicine, The Ohio State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Microscopically, in an acute infarct, nephrons (including tubules, glomeruli, and interstitium) in the central zone of the infarct become necrotic (Fig. 11-68). At the periphery of the infarct, only the proximal tubules, because of their high metabolic rate, are necrotic; the glomeruli tend to be spared. After a couple of days, the margin of the necrotic zone contains an inflammatory infiltrate consisting largely of neutrophils and fewer macrophages and lymphocytes (Fig. 11-68). Capillaries adjacent to the necrotic area are notably engorged with blood. Healing of the infarcted area occurs by lysis and phagocytosis of the necrotic tissue and replacement by fibrous connective tissue, which matures to a discrete scar. Scars range from linear to broad depending on the size of the acute infarct. Septic infarcts are initially hemorrhagic, but because of the presence of pyogenic bacteria, the necrotic tissue undergoes liquefactive necrosis and the infarcts can eventually develop into abscesses and ultimately into substantial scars. Septic infarcts often fail to respect a solely cortical or medullary pattern of distribution due to the extensive local inflammation that they generate.

675

676

**Fig. 11-68 Acute infarct, kidney, cortex, dog.** Note the acute infarct with a central zone of coagulation necrosis surrounded by a zone of hyperemia and hemorrhage (*arrows*). H&E stain. (Courtesy Dr. S.J. Newman, College of Veterinary Medicine, University of Tennessee.)

### 11.2.6.4 PAPILLARY (MEDULLARY CREST) NECROSIS

Necrosis of the renal papillae, or their counterpart, the medullary crest, is a response of the inner medulla to ischemia. Papillary necrosis can be a primary or secondary lesion. Papillary necrosis occurs as a primary disease in animals treated with nonsteroidal antiinflammatory analgesic drugs and is analogous to analgesic nephropathy in human beings. The primary disease occurs quite frequently in horses treated for prolonged periods with phenylbutazone or flunixin meglumine. It is of potential importance in dogs and cats because of accidental ingestion of or treatment with ibuprofen, aspirin, or acetaminophen at excessive dosages. Drugs associated with papillary necrosis are sometimes referred to as “papillotoxins.” The medullary interstitial cells are the primary targets of papillotoxins. These cells have a key role in synthesis of prostaglandins, antihypertensive factors, and the glycosaminoglycan matrix of the medullary interstitium. Interstitial cell

## Pathologic Basis of Veterinary Disease, 4th Edition

---

damage decreases prostaglandin synthesis, which reduces normal blood flow and causes ischemia, increases tubular transport, and modifies the interstitial matrix; the net effect is degenerative changes in tubular epithelial cells in the inner medulla. In addition to its inhibition of prostaglandin biosynthesis, acetaminophen also causes direct oxidative damage to medullary tubular epithelium after covalent binding to the cells, further enhancing necrosis of the renal papillae.

Secondary papillary necrosis results from the following:

- A. Reduced blood flow in vasa recta
  - 1. Glomerular lesions restricting blood flow—amyloid, hyalinization
  - 2. Compression of vasa recta within the medulla
    - a. Interstitial fibrosis—chiefly in the outer medulla, secondary to ischemia (see later discussion)
    - b. Interstitial renal medullary amyloidosis (cats)
    - c. Pyelitis—ascending tubular and interstitial inflammation, edema, and fibrosis
- B. Compression of renal papilla by factors external to the kidney
  - 1. Intrapelvic pressure secondary to:
    - a. Pelvic calculi
    - b. Lower urinary tract obstruction
    - c. Vesicoureteral reflux

The outer medulla and the cells of the thick ascending loop of Henle in particular are the least well perfused of any zones of the kidneys. This is because the medulla has little direct perfusion; instead, most of the medullary blood supply comes from the cortex, through the vasa recta. Because of this limited blood flow, in addition to the high metabolic medullary cellular demand, any lesion or disease process that further reduces medullary blood flow can cause ischemic necrosis (infarction) of the papillae. Additionally, the high metabolic demand for cell transport and the maintenance of an ion gradient to enhance urinary concentration makes this area particularly vulnerable. This is most evident following ischemic tubular damage where swollen endothelial and tubular epithelial cells, in conjunction with neutrophil adhesion in small vessels, upset the balance of oxygenation and energy demand by the outer medullary tubular cells. Medullary blood flow is ultimately balanced through levels of vasodilators, such as prostaglandin, nitric oxide, and adenosine, and vasoconstrictors, such as endothelin and angiotensin II.

Typically, acute lesions are irregular, discolored areas of necrotic inner medulla sharply delineated from the surviving medullary tissue (Fig. 11-69). The affected tissue, which is undergoing coagulation necrosis, is yellow-gray, green, or pink. With time, the necrotic tissue sloughs, resulting in a detached, friable, and discolored tissue fragment in the pelvis. The remaining inner medulla is usually narrowed and attenuated. Overlying cortex can be somewhat shrunk because of atrophy of some of the nephrons caused by blockage of the tubules secondary to the chronic medullary changes. Small pieces of sloughed necrotic medullary tissue pass inconsequentially into the ureter. However, large pieces of sloughed tissue can obstruct the ureter, causing hydronephrosis, or form a nidus for precipitation of minerals, resulting in the formation of pelvic or

676

677

## Pathologic Basis of Veterinary Disease, 4th Edition

ureteral calculi. Papillary necrosis is usually an incidental finding at necropsy and rarely leads to progressive renal damage and failure.

**Fig. 11-69 Papillary (medullary crest) necrosis, chronic nonsteroidal antiinflammatory drug treatment, kidney, dorsal section, horse.** Acute coagulation necrosis of the medullary crest and inner medulla (*greenish areas*). There is also hemorrhage of the outer medulla (*arrows*). The term *papillary necrosis* is retained for all animals, although only the pig and cow have distinct renal papillae. In other animals, these have fused to form the medullary crest. (Courtesy Dr. A. Confer, College of Veterinary Medicine, Oklahoma State University.)

### 11.2.7 NEOPLASIA

The prevalence of primary renal neoplasms in domestic animals is less than 1% of the total neoplasms reported. They are usually unilateral and can be of epithelial, mesenchymal, or embryonal origin.

#### 11.2.7.1 EPITHELIAL TUMORS

Renal adenomas are rare, benign, epithelial neoplasms consisting of proliferating renal cortical epithelial cells. They are incidental findings at necropsy and usually appear as a small (1 to 3 cm), white-to-yellow, solitary, well-circumscribed, nonencapsulated mass in the cortex. Microscopically, adenomas are composed of solid sheets, tubules, or papillary proliferations of cuboidal epithelial cells that are uniform in size and have granular eosinophilic cytoplasm and small, round to oval nuclei. Mitotic figures, necrosis, and fibrosis are rare. These incidental tumors are clinically asymptomatic.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Oncocytomas are rare benign epithelial tumors that can occur in a variety of tissues. Grossly, renal oncocytomas are tan, homogeneous, well-encapsulated masses composed of oncocytes. Histologically, they are composed of large eosinophilic granular round cells with condensed round nuclei. Ultrastructurally, they are characterized by numerous prominent cytoplasmic mitochondria. Their origin in the kidney is speculated to be from the intercalated cells of the collecting ducts. These tumors are clinically asymptomatic.

Renal carcinomas are the most common primary renal neoplasms and occur most frequently in older dogs. The specific causes of renal adenocarcinomas in human beings are well determined compared with those in animal species, but several mechanisms have been proven in natural animal disease or experimental models. These include the following:

1. Viruses—herpesvirus oncogenes are known to play a major role in formation of virally induced adenocarcinoma (Lucke's tumor) in the kidney of frogs, and avian erythroblastosis virus [strain ES4] induces renal adenocarcinomas in chickens.
2. Chemical carcinogens—these have been postulated to be causative and typically exert their neoplastic influence by direct DNA damage or inhibition of DNA synthesis or repair.
3. Autosomal dominant gene mutations in Eker rats—these predispose these rats to bilateral renal cell carcinoma and a variety of other secondary cancers, resembling the human von Hippel-Lindau disease.

These neoplasms are usually large (up to 20 cm in diameter), spherical to oval, and firm. They often are pale yellow and contain dark areas of hemorrhage and necrosis and foci of cystic degeneration. The masses usually occupy and obliterate one pole of the kidney and grow by expansion, compressing the adjacent normal renal tissue (Fig. 11-70). Histologic types include papillary, tubular, and solid (Fig. 11-70, C), with solid variants being the most poorly differentiated. Metastasis to the lungs, lymph nodes, liver, and adrenal occur frequently. Renal carcinoma has been associated with paraneoplastic conditions, principally polycythemia. This is because of concurrent overexpression of erythropoietin, which increases bone marrow production of red blood cells.

A variant of the typical renal carcinoma has been seen in German shepherd dogs in conjunction with nodular dermatofibrosis. The lesions are hereditary and consist of multifocal, bilateral, renal cystadenomas or cystadenocarcinomas. Grossly, these resemble the adenocarcinomas described previously, but cysts are much more prominent. The neoplastic cells form solid sheets, tubules, or papillary growth patterns, and the cells in the carcinomas are more atypical and anaplastic. Cells vary in shape from cuboidal and columnar to polyhedral, vary in size, and have clear or granular eosinophilic cytoplasm. Nuclei range from small, round, granular, and uniform to large, oval, vesicular, and pleomorphic. Mitotic figures are numerous. These neoplasms have a moderate fibrovascular stroma.

677

**Fig. 11-70 Renal carcinoma, kidney, dog.** **A**, The neoplasm is pale white with reddish areas, lobulated, and has infiltrated and replaced one pole of the kidney. **B**, Dorsal section. The normal architecture of the cranial half of the kidney has been obliterated by the tumor, which has hemorrhaged caudally into the adjacent kidney and subcapsularly. **C**, The tumor consists of anaplastic renal epithelial cells, typical of the solid, more poorly differentiated variant of renal carcinoma. H&E stain. (**A** and **B**, Courtesy College of Veterinary Medicine, University of Illinois. **C**, Courtesy Dr. S.J. Newman, College of Veterinary Medicine, University of Tennessee.)

Transitional cell papillomas and transitional cell carcinomas arise in the renal pelvis and lower urinary tract and, when large, can obstruct urinary outflow. Such carcinomas can invade into the kidney and typically carry a poor prognosis. The morphologic features of transitional cell neoplasms will be discussed later with the urinary bladder neoplasms (see Lower Urinary Tract).

### 11.2.7.2

#### MESENCHYMAL TUMORS

Occasionally, fibromas, fibrosarcomas, or hemangiosarcomas originate in the kidneys. Primary renal sarcomas are rare. Microscopically, in hemangiosarcomas, neoplastic spindle cells are arranged in solid

## Pathologic Basis of Veterinary Disease, 4th Edition

---

interlacing bundles and whorls or as variable channels lined by neoplastic endothelium. Cellular pleomorphism and mitotic rate are relatively low.

11.2.7.3

### METASTATIC TUMORS

Carcinomas and sarcomas (metastatic tumors) arising in other organs can metastasize to the kidneys and are characteristically composed of randomly scattered multiple nodules, usually involving both kidneys (Fig. 11-71). Renal lymphosarcoma occurs with some frequency in cattle and cats, particularly as part of generalized or multicentric lymphosarcoma, which is secondary to retrovirus infection. These neoplastic foci appear as single or multiple homogeneous gray-white nodules (Fig. 11-71, *B and E*) or as diffuse lymphomatous infiltrates that cause uniform enlargement and pale discoloration of the kidney (Fig. 11-71, *C*). In cats, renal lymphosarcoma must be differentiated histologically from the necrotizing, fibrinous, and granulomatous renal vasculitis of feline infectious peritonitis and less commonly systemic cryptococcosis (Fig. 11-71, *E*). Microscopically, neoplastic lymphocytes form obliterative sheets of cells within the renal parenchyma, unrelated to the vasculature (Fig. 11-71, *F*). Neoplastic lymphocytes have distinct cellular borders, moderate amounts of basophilic cytoplasm, and large round vesicular nuclei with variable prominence to the nucleoli. Lymphosarcoma of the kidney can be treated with some success with chemotherapeutics.

678

680

**Fig. 11-71 Primary and metastatic renal tumors, kidney.** **A**, Metastatic mast cell tumor, dorsal section, dog. Multiple pale tan, raised nodules are randomly scattered throughout the renal cortex. **B**, Lymphoma (lymphosarcoma), cow. Multifocal raised pale white nodules are typical of nodular renal lymphosarcoma. **C**, Lymphoma (lymphosarcoma), dorsal section, cat. Note the pale white areas in the cortex, which bulge from the surface. This lesion can be confused with the granulomatous vasculitis of renal feline infectious peritonitis, thus warranting histologic evaluation. **D**, Systemic cryptococcosis (*Cryptococcus neoformans*), cat. This is not a neoplasm, but the multiple pale, occasionally raised nodules can be confused with the nodular form of lymphoma (Fig. 11-71, C), thus requiring histologic examination. **E**, Lymphoma (lymphosarcoma), dorsal section, bovine. Multiple coalescing pale white nodules are present throughout the cortex. **F**, Lymphoma (lymphosarcoma), cow. Neoplastic lymphocytes infiltrate and distend the renal interstitium. H&E stain. Read, College of Veterinary Medicine, Texas A&M University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **D**, Courtesy Dr. S.J. Newman, College of Veterinary Medicine, University of Tennessee. **E**, Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University; and Dr. J. Edwards, College of Veterinary Medicine, Texas A&M University. **F**, Courtesy Dr. J. Simon, College of Veterinary Medicine, University of Illinois.)

### 11.2.7.4 TUMORS OF EMBRYONAL ORIGIN

Nephroblastomas (embryonal nephroma or Wilms tumor) are common renal neoplasms of pigs and chickens, and are usually recognized as incidental findings at slaughter. They occur in cattle and dogs as well, but less frequently. These neoplasms arise from metanephric blastema and thus occur in young animals. It is speculated that neoplasms result from malignant transformation during normal nephrogenesis or from neoplastic transformation of nests of embryonic tissue that persist in the postnatal kidneys. At necropsy, nephroblastomas can be solitary or multiple masses that often reach a great size and in which recognizable renal tissue can be difficult to detect. They usually are soft to rubbery and gray with foci of hemorrhage. On a cut surface, they are often lobulated. Because nephroblastomas arise from primitive pluripotent tissue, histologic features vary but are morphologically similar to the developmental stages of embryonic kidneys. Characteristically, three components—including primitive, loose myxomatous mesenchymal tissue interspersed with primitive tubules lined by elongated, deeply staining cells and structures that resemble primitive glomeruli—are present. Nests of cells resembling the metanephric blastema can be present. Nephroblastomas also have mesenchymal components, such as cartilage, bone, skeletal muscle, and adipose tissue. Clinically, these are usually incidental findings, except in dogs, in which they rarely present as spinal dysfunction, the result of spread to the vertebral canal with secondary spinal cord compression.

### 11.3 DISEASES OF THE LOWER URINARY SYSTEM

#### 11.3.1 DEVELOPMENTAL ANOMALIES

##### 11.3.1.1 APLASIA AND HYPOPLASIA

Ureteral aplasia (agenesis) is the lack of formation of a recognizable ureter, and hypoplasia is the presence of a notably small-diameter ureter. Agenesis of the ureters is due to failure of the ureteral bud to form, and may be unilateral or bilateral. Both conditions are rare. If these defects occur alone, then there is disruption of urinary flow from the kidney to the urinary bladder, resulting in obstructive diseases such as hydronephrosis. If these defects occur with concurrent renal aplasia, then they are clinically silent when unilateral and life threatening when bilateral.

##### 11.3.1.2 ECTOPIC URETERS

Ectopic ureters are ureters that may empty into the urethra, vagina, neck of the bladder, ductus deferens, prostate, or other secondary sex glands. There are two possible causes:

1. The ureteral bud arises too far craniad to be incorporated into the urogenital sinus.
2. The differential growth of the sinus is abnormal, and the ureter fails to migrate to its usual location.

Ectopic ureters are more subject to obstruction or infection, and thus they predispose animals to pyelitis and pyelonephritis. Otherwise, histologically these are normal. This condition is found most frequently in dogs and certain breeds, especially the Siberian husky, are at greater risk. Affected animals present clinically with urinary incontinence and consequent urine dribbling.

##### 11.3.1.3 PATENT URACHUS

The most common malformation of the urinary bladder is patent urachus (pervious urachus). This lesion develops when the fetal urachus fails to close and therefore forms a direct channel between the bladder's apex and the umbilicus. Failure of the urachal remnant and the umbilical arteries and vein to involute is frequently observed in cases of "neonatal" omphalitis, in which abscess formation may result in a patent urachus. Patent urachus has also occurred because of congenital urethral obstruction. Increased bladder pressure because of the obstruction forces urine out into the urachus. Rupture of the urachus causes uroperitoneum. The condition must be differentiated from perinatal rupture of the bladder. Foals are affected most often and animals with this defect dribble urine from the umbilicus. Diverticula of the bladder may be primary or acquired and secondary to partial obstruction of the outflow of urine or the result of pressure changes exerted during normal contractions. Occasionally, during urachal closure, the mucosa closes but closure of the bladder musculature is incomplete. When this occurs, a bladder diverticulum (outpouching) of the apex of the bladder can develop. Urine stasis can occur in the diverticulum, predisposing the animal to cystitis or urinary calculi.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 11.3.2 OBSTRUCTIVE DISEASES

#### 11.3.2.1 UROLITHIASIS

Urinary calculi (uroliths) are concretions formed anywhere in the urinary collecting system, and although some clearly originate in the lower urinary tract or as microscopic calculi in the renal collecting tubules, the point of development of most is not known. Uroliths are commonly found in the ureter, followed by any portion of the lower urinary tract and least commonly in the renal pelvis (accounting for 1% to 4 % of canine uroliths). The diseases caused by uroliths are among the most important urinary tract problems of domesticated animals, especially cattle, sheep, dogs, and cats, and are of lesser importance in horses and pigs.

680

681

Calculi are grossly visible aggregations of precipitated urinary solutes, principally mineral admixed with urinary proteins and proteinaceous debris. Calculi typically are hard spheres or ovoids, with a central nidus, surrounded by concentric laminae (“stone”), an outer shell, and surface crystals. Many calculi contain significant quantities of “contaminants,” such as calcium oxalates in “silica” calculi; few are relatively pure. Large renal pelvic calculi classically have a “staghorn” appearance because they take the shape of the renal calyces in animal species that have true calyces (Fig. 11-72). These calculi predispose affected animals to pyelitis and pyelonephritis. Urinary bladder calculi can be single or multiple, variable in size (2 mm to 10 cm), and sometimes are composed of a fine, sandlike material, which causes cloudy urine (Fig. 11-73). Calculi can have smooth or rough surfaces; and may be solid, soft, or friable. Calculi vary in color depending on their composition; however, color is variable among calculi even of the same composition. The calculi can be white to gray (e.g., struvite and oxalate), yellow (e.g., urate, cystine, benzocoumarin, and xanthine), or brown (e.g., silica, urate, and xanthine), depending on their composition.

Small calculi may be voided in the urine, but typically calculi cause urinary obstruction. This is more common in males because of their long and narrow-diameter urethra. The most common sites of lodgment of urethral calculi vary with the animal species. In male cattle, calculi lodge in the urethra at the ischial arch and at the proximal end of the sigmoid flexure; in rams and wethers, the urethral process (vermiform appendage) is the most common site (Fig. 11-74, A); and in dogs, calculi lodge proximal to the base of the os penis (Fig. 11-74, B). At the site where calculi lodge, there is local pressure necrosis, ulceration of the mucosa, and acute hemorrhagic urethritis. Because the urethral sites are prone to rupture, hydronephrosis following urethral obstruction is less common than with unilateral long-standing ureteral impaction. In cats, fine struvite crystals (sand) in a rubberlike protein matrix can fill the entire urethra, and such calculi are typical for the disease called feline urologic syndrome (Fig. 11-74, C). When obstruction or dysuria occurs in females, calculi are usually large and located in the renal pelvis or urinary bladder (Fig. 11-75).

Fig. 11-72 **Urolithiasis, kidney, dorsal section, dog.** A calculus fills and distends the renal pelvis (*arrows*) and has caused pressure atrophy of the medulla. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 11-73 **Urolithiasis, urinary bladder, dog.** Multiple smooth calculi are present in the urinary bladder. The bladder wall is diffusely thickened. (Courtesy Dr. A. Confer, College of Veterinary Medicine, Oklahoma State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Factors that are either important in predisposing to calculus formation or in precipitating disease include the following:

1. Calculus precursors material in urine in quantities sufficient to be precipitated.
2. Substance is metabolized in an unusual way, as is uric acid in Dalmatian dogs.
3. Substance may be processed abnormally by the kidney (hereditary defects), as with cystine or xanthine.
4. Abnormally high levels of a substance are encountered in the diet, such as the following:
  - a. Silicic acid in native pastures 681
  - b. Phosphate in milo or sorghum products (struvites) 682
  - c. Estrogens in subterranean clover (clover stones [benzocoumarin] or carbonates)
  - d. Magnesium in commercial dry cat food
  - e. Oxalate in oxalate-accumulating plants (oxalates)
5. Abnormally low levels of a substance are encountered in the diet, such as the following:
  - a. Vitamin A (equivocal evidence that vitamin A deficiency may produce metaplastic change in the urinary tract epithelium that creates a nidus of calculus formation following desquamation of epithelium)

Regardless of the type of calculus, certain factors are more or less important in calculus formation; these are as follows:

1. Urinary pH, in terms of its optimum for solute precipitation (oxalates at acid pH and struvites and carbonates at alkaline pH)
2. Reduced water intake, in relation to the degree of urine concentration and mineral supersaturation
3. Bacterial infection of the lower urinary tract (struvite calculi in dogs)
4. Obstruction
5. Structural abnormalities of the lower urinary system
6. Foreign bodies (suture, grass awn, catheter, needle), or a conglomerate of bacterial colonies, exfoliated epithelium, or leukocytes, which can serve as a nidus for precipitation of mineral constituents
7. Drugs excreted in the urine, which may act as a nidus for calculus formation (e.g., sulfonamides and tetracyclines)

**Fig. 11-74 Urolithiasis, penile urethra.** **A**, Sheep. Multiple calculi are present in the penile urethra (*arrow*) and the urethral process (vermiform appendage). **B**, Ventral aspect, dog. Calculi have lodged in the urethra proximal to the caudal end of the os penis (*arrow*). **C**, Cat. Calculi are present throughout the penile urethra, several just caudal to the external urethral orifice at tip of the penis. (**A** and **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **C**, Courtesy College of Veterinary Medicine, University of Illinois.)

Supersaturation of urine with respect to the components of stone-forming salts is the essential precursor to initiation of urolith formation (nucleation). Supersaturation may be in the unstable range where precipitation occurs spontaneously (homogeneous nucleation) or the metastable range where precipitation occurs by epitaxy (one type of crystal grows on the surface of another type; heterogeneous nucleation).

Although it was formerly thought that urinary proteins such as uromucoid, which make up 5% to 20% or more of some calculi, were preeminent initiators of crystal formation in the metastable range, it is now believed that in many cases either co-precipitation of proteins and minerals occurs or that proteins are adsorbed onto formed crystals. It is possible that crystals of one salt, for which urine is supersaturated in the unstable range, cause induction of crystals of another salt for which supersaturation is apparently stable.

682

Fig. 11-75 **Hemorrhagic urocystitis (feline urologic syndrome) urinary bladder, cat. A**, Obstructive urolithiasis. The bladder is overdistended and turgid as the result of urethral obstruction. Note the serosal and intramuscular ecchymotic and suffusive hemorrhages at the neck and apex of the bladder. **B**, Urolithiasis, acute hemorrhagic cystitis. The severe diffuse transmural hemorrhage throughout the urinary bladder wall is secondary to blockage of the urethra by calculi and distension of the urinary bladder. (**A** and **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Crystals are much more common in urine than are calculi. Even though equine urine is normally supersaturated with calcium carbonate, and crystalluria is normal, horses experience a low prevalence of calculi. The factors, which promote or prevent crystal growth and crystal aggregation are poorly understood. Experimentally, high concentrations of urinary inorganic pyrophosphate and magnesium are important inhibitors of calcium phosphate and calcium oxalate crystallization. Pyrophosphate also inhibits aggregation of calcium phosphate crystals. Certain urinary macromolecules, probably glycosaminoglycans, are also strong inhibitors of crystal aggregation in experimental systems. Deficiency of inhibitors of crystallization may be important in calcium oxalate and calcium phosphate calculogenesis (crystallization-inhibition theory of urolith initiation).

Discussion of calculogenesis for a few specific calculi of importance is warranted.

### 11.3.2.1.1

#### Silica Calculi

Silica calculi (75% silica dioxide) are very common in pastured ruminants. Certain grasses contain as much as 4% to 5% silica; most of the silica is insoluble except that which is in the cell sap (unpolymerized silicic acid). After absorption, silica is returned to the gut in digestive secretions; less than 1% of dietary silica is excreted in urine and up to 60% is resorbed from the filtrate. However, when urine production is very low, the concentration of silicic acid excretion in urine may reach five times the saturation level. Precipitation from solution requires other substances in the urine. Silica calculi are hard, white to dark-brown, radiopaque, often laminated, large-diameter stones and are a major cause of urinary tract obstruction. Calculus formation is reduced to subclinical levels by adding sodium chloride to the ration, acidifying the diet, or reducing the dietary calcium to phosphorus ratio.

### 11.3.2.1.2

#### Struvite Calculi

Struvite is magnesium ammonium phosphate hexahydrate ( $\text{Mg NH}_4\text{PO}_4 \cdot 6\text{H}_2\text{O}$ ), formerly referred to by the misnomer “triple phosphate.” Struvite calculi are important in dogs (the most common type of calculus), cats, and ruminants. Females are more commonly affected because of the common association of these stones (infection calculi) with lower urinary tract infections. Bacterial ureases can induce supersaturation of urine with struvite by increasing urine pH, which decreases struvite solubility and increases ionization of trivalent phosphate, both of which favor calculus formation. A high incidence of struvite calculi in miniature schnauzers may be related to a familial susceptibility to urinary tract infections. Struvite stones are white or gray, radiopaque, chalky, usually smooth, and easily broken. They may be single and large, or numerous and sandlike.

In cats, one manifestation of feline lower urinary tract disease (FLUTD) is struvite urolithiasis, occurring subsequent to feeding calculogenic diets containing 0.15% to 1.0% dry weight magnesium to normal cats. Coagulase-positive staphylococci and other bacteria may be cultured from the urine or calculi of some affected cats, and the formation of infection-induced struvite calculi is similar to that mentioned previously for dogs; these calculi are much less common than sterile struvite uroliths in cats.

683

Of considerably more importance than discrete calculi are the amorphous accumulations of protein, cellular debris, and struvite crystals that form sabulous (gritty or sandy) urethral plugs (a condition formerly referred to as feline urologic syndrome [FUS]) in middle-aged, castrated male cats. It is thought to result from concomitant occurrence of urinary tract inflammation and the presence of various types of urine crystals. The obstructive material may be either struvite “sand” and/or rubberlike protein matrix, the

684

## Pathologic Basis of Veterinary Disease, 4th Edition

---

latter of which is composed of Tamm-Horsfall mucoprotein (secreted by the cells lining the ascending limb of the loop of Henle and the distal tubules), albumin, globulins, and cellular debris. The inflammatory component of plugs in cats may be the product of infection with the following:

1. Viruses, including feline cell-associated herpesvirus (a strain of bovine herpesvirus 4), feline syncytia-forming virus, and feline calicivirus
2. Bacteria
3. Fungi

The incidence of urethral plugs has decreased as more cats have been fed magnesium-restricted and/or low pH diets.

### 11.3.2.1.3

#### Oxalate Calculi

Oxalate calculi occur as the calcium oxalates, whewellite (calcium oxalate monohydrate) and weddellite (calcium oxalate dihydrate). Their development is not well understood, but hypercalciuria and hyperoxaluria are involved. Oxalic acid is synthesized from glyoxylic and ascorbic acid, and oxalates may be ingested in certain foods and plants. Dietary magnesium and citrate inhibit the formation of calcium oxalate uroliths by forming soluble intestinal complexes with oxalate and calcium. Oxalate calculi are hard, heavy, white or yellow, and are typically covered with jagged spines, although some are smooth. They tend to be large and solitary stones in the bladder.

In ruminants, exposure to oxalate-containing plants predisposes these animals to oxalate nephrosis and acute death and thus only rarely results in oxalate uroliths in the lower urinary tract. The primary symptoms in ruminants result from the following:

1. Chelation of calcium to produce hypocalcemia
2. Calcification of vessel walls throughout the body, predisposing to widespread vascular infarction and hemorrhage
3. Calcification of renal tubules, resulting in tubular obstruction and renal failure

In dogs, oxalate calculi are second to struvite calculi in prevalence and are of increasing importance, but little is known of their origins. Calcium oxalate and calcium phosphate (hydroxyapatite or calcium apatite) calculi occur in dogs:

1. With primary hyperparathyroidism
2. With hypercalcemia
3. With hyperadrenocorticism
4. Following exogenous steroid administration

Males are more frequently affected than females, and calculi are seen more commonly in older animals. The miniature schnauzer, bichon frisé, Lhasa apso, Yorkshire terrier, Shih Tzu, and miniature poodle are breeds at increased risk.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The prevalence of oxalate uroliths in cats has increased notably from the early 1980s to the present. This increase has been accompanied by a notable decline in the prevalence of struvite uroliths. The underlying cause for oxalate uroliths in cats is unknown but is likely related to diet. Several dietary factors can contribute to calciuria (high levels of calcium in the urine) including the following:

1. High percentage of animal-source protein
2. Low magnesium
3. High sodium chloride
4. Diets formulated to acidify urine

Oxalate uroliths in cats have been associated with parathyroid neoplasia, as in dogs.

11.3.2.1.4

### Uric Acid and Urate Calculi

Uric acid is a metabolite of purine metabolism. These calculi contain either ammonium urate with some uric acid and phosphate or sodium urate. Urate stones are most common in dogs, especially male Dalmatians, because they excrete high concentrations of uric acid in their urine. This is due to defective hepatocellular uptake of uric acid from the blood (hepatic uricase levels are normal), which results in incomplete conversion of uric acid to allantoin, a more soluble product of purine metabolism. This defect is an inherited autosomal recessive trait. Additionally, the defective transport system in the renal tubules, which prevents reabsorption of uric acid from glomerular filtrate, and the active tubular secretion both contribute to urine supersaturation.

Predisposing factors for urolith formation include the following:

1. Hyperuricemia
2. Hyperammonemia
3. Hyperuricosuria
4. Hyperammonuria
5. Aciduria
6. Genetic predisposition

Dogs with portosystemic shunts have ammonium biurate crystals in their urine, and they may have urate-containing calculi in the kidneys and bladder. These calculi are usually multiple, hard, concentrically laminated, brown-green, and moderately radiodense. In the bladder, they are frequently spherical and less than 5 mm in diameter.

684

11.3.2.1.5

### Xanthine Calculi

Xanthine is another metabolite of purines. It seldom appears in urine because normally it is degraded by xanthine oxidase to uric acid. As in human beings, two pathogenic forms exist in dogs. The primary form

685

## Pathologic Basis of Veterinary Disease, 4th Edition

is inherited as an autosomal recessive trait and is due to an inborn enzyme defect in xanthine oxidase. This hepatic enzyme catalyses two sequential steps in degradation of purines:

1. Conversion of hypoxanthine to xanthine
2. Conversion of xanthine to uric acid; this form has been noted most often in dachshunds and recently in a family of cavalier King Charles spaniels.

The secondary form (iatrogenic) is the more common in dogs, especially Dalmatians, and is usually the result of previous treatment with allopurinol, which binds to and inhibits the action of xanthine oxidase. Additionally, cases in sheep were circumstantially related to deficiency of molybdenum in unimproved pasture; molybdenum is a component of the xanthine oxidase enzyme.

### 11.3.2.1.6

#### Cystine Calculi

Many cystine calculi consist of pure cystine; others may also contain calcium oxalate, struvite, brushite (calcium hydrogen phosphate dihydrate), and complex urates. Cystine stones occur in dogs and rarely in cats. Cystinuria occurs in both males and females, but cystine calculi and urinary obstruction occur almost exclusively in males. Predisposed breeds include Newfoundlands, dachshunds, bulldogs, mastiffs, basset hounds, and Tibetan spaniels. The mode of inheritance of cystinuria is unknown in most breeds of dogs, but it is transmitted as a simple autosomal recessive trait in Newfoundlands.

**Fig. 11-76 Acute cystitis, urinary bladder. A,** Mucosal and serosal surfaces, calf. Patchy areas of ulcerated mucosa are interspersed with areas of hemorrhagic mucosa. Note the subserosal hemorrhages (*top*). **B,** The mucosa has been denuded of transitional epithelium. There are marked mucosal and submucosal infiltrates of neutrophils, which extend into the adjacent tunica muscularis. Congested vessels (*arrow*) and hemorrhages are in the outer tunica muscularis and subserosa. H&E stain. (**A**, Courtesy Dr. A. Confer, College of Veterinary Medicine, Oklahoma State University. **B**, Courtesy Dr. S.J. Newman, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Although blood cystine concentrations are normal, an inborn error of metabolism in affected dogs results in high levels of urinary cystine because of defective proximal tubular reabsorption from glomerular filtrate. Many dogs with cystinuria also have high concentrations of other amino acids in their urine, but these are more soluble than cystine. Cystine precipitates in acid urine, but factors other than urinary pH probably are important in the genesis of cystine stones because dogs with crystalluria do not always form them. Cystine calculi are small and irregular, soft and friable, waxy, and light yellow to red-brown turning to green on exposure to daylight.

At necropsy, animals that have died of urinary obstruction have greatly distended (Fig. 11-76, A), turgid, or ruptured bladders and dilated ureters and renal pelves. The bladder wall is thin and often has mucosal to transmural ecchymoses or diffuse hemorrhage (Fig. 11-76, B). When urine is released from the bladder, either because of rupture or incision at surgery or necropsy, the wall of the bladder is flaccid, the mucosa is often ulcerated, and the urine contains blood clots. Mucosal ulceration, localized lamina propria hemorrhage, and mucosal necrosis are usually present in the ureter, bladder, or urethra adjacent to an obstructive calculus. If the bladder ruptures antemortem, blood clots and fibrin are at the site of rupture, and in some cases there is an acute, localized chemical (urine-induced) peritonitis.

Microscopically, inflammation and hemorrhage are present in the lower urinary tract. Lesions are most severe in cases in which obstruction has been complete. The mucosa is usually ulcerated, and areas of hyperplastic transitional epithelium are interspersed with goblet cells. The lamina propria is usually infiltrated with inflammatory cells. Neutrophils are present at foci of ulceration, and lymphocytes and plasma cells infiltrate perivascularly or uniformly throughout the lamina propria. Hemorrhage is transmural, but is most evident in the mucosa and can cause separation of the smooth muscle bundles. Degeneration and necrosis of smooth muscle occurs in severe cases.

Urolithiasis can cause urinary obstruction or traumatic injury to the urinary bladder mucosa. Lesions of the urinary bladder are manifested clinically as difficult or painful urination (stranguria; dysuria), with or without hematuria. Small calculi may be voided in the urine, but typically calculi cause urinary obstruction. In males, dysuria can result from large calculi, but urinary tract obstruction with uremia most commonly occurs because of obstruction of the urethra with small calculi.

### 11.3.2.2 HYDROURETER AND HYDROURETHRA

Hydroureter and hydrourethra refer to dilation of the ureter and urethra, respectively, and are caused by obstruction of urine outflow by blockage of the ureter(s) or urethra by calculi, chronic inflammation, or luminal or intramural neoplasia. Hydroureter can be unilateral or bilateral. Depending on the location of the obstruction, hydronephrosis, hydroureter, and hydrourethra can occur concurrently (see Hydronephrosis). Histologic findings demonstrate little change except for a greater cross-sectional diameter of the ureter or urethra and compression of their lining epithelium. The clinical signs of these conditions are related to obstruction.

### 11.3.3 INFLAMMATORY DISEASES

#### 11.3.3.1 ACUTE CYSTITIS

Inflammation of the urinary bladder (cystitis) is common in domestic animals. Because inflammation of the ureter (ureteritis) or urethra (urethritis) in the absence of cystitis is rare, this discussion concentrates on

## Pathologic Basis of Veterinary Disease, 4th Edition

---

cystitis. The causes of acute cystitis are varied; however, for all animal species, bacterial infection is the most common cause. Cystitis may be acute or chronic. Normally the bladder is resistant to infection, and contaminating bacteria are quickly eliminated by the normal flow of normal urine. Predisposition to urinary tract infection (UTI) occurs when there is stagnation of urine because of obstruction, incomplete voiding at micturition, or urothelial trauma. Other risk factors for UTI include: catheterization, vaginoscopy, vaginitis, urinary incontinence, or prolonged administration of medications such as antibiotics that induce bacterial resistance. Bacterial cystitis is more common in females because their relatively short urethra provides a shorter barrier to ascending infections than the longer, narrow diameter of the male urethra. The bacterial species most commonly associated with cystitis are uropathogenic *Escherichia coli* ( $\alpha$ -hemolysin-producing strains) in all animal species; *Corynebacterium renale* in cattle; *Eubacterium* (*Corynebacterium*) *suis* in pigs; and *Klebsiella* sp. in horses. In addition, *Proteus* sp., *Streptococcus* sp., and *Staphylococcus* sp. have been isolated from cases of cystitis in several animal species.

Except for the distal urethra, the lower urinary tract is normally free of bacteria. Sterility of the urinary bladder is maintained through normal repeated voiding of urine and because of the antibacterial properties of urine. These antibacterial properties are attributable to the following:

1. The acidic urine of carnivores
2. Secretory IgA
3. Secreted mucin that inhibits bacterial adhesion
4. The large concentration of urea and organic acids
5. High urine osmolality

Cystitis occurs when bacteria are able to overcome normal defense mechanisms and adhere to or invade (colonize) the urinary bladder mucosa. Several factors can enhance colonization and predispose animals to cystitis. Colonization is more likely for strains of bacteria that express molecules on their surfaces that enhance adhesion (e.g., the P and type 1 fimbriae of certain strains of *Escherichia coli*). Retention of urine as a result of obstruction or neurogenic causes such as spinal cord diseases often leads to cystitis.

Trauma to the urinary bladder mucosa due to calculi, faulty catheterization, or other causes can cause erosion and hemorrhage and predispose to bacterial invasion of the lamina propria. Hydrolysis of urea by urease-producing bacteria, such as *Corynebacterium renale* and *Eubacterium suis*, releases excessive ammonia that can damage the mucosa. Bacterial growth can be enhanced when glucosuria is present, such as in diabetes mellitus. Compromise of the host immune system as found with infection by the feline immunodeficiency virus can increase susceptibility to bacterial cystitis. Other bacterial virulence factors, such as the *Escherichia coli* hemolysin, enhance pathogenicity and help bacteria overcome antibacterial factors of the urinary bladder and urine.

Once bacteria gain access to the lamina propria, they cause vascular damage and inflammation. Acute cystitis is often grossly described as hemorrhagic, fibrinopurulent, necrotizing, or ulcerative, and these changes are often sequential over time. Vascular damage predisposes to hemorrhage, leakage of fibrin and if severe, ischemic necrosis of the bladder. This is often accompanied by mucosal ulceration. Neutrophils are present as a component of vascular damage and in any lesion with accompanying bacterial colonization. However, in each case, components of several of these processes are present. The urinary bladder wall often is thickened by edema and an inflammatory cell infiltrate and is diffusely or focally hemorrhagic. Hemorrhage is most common when obstruction is concurrently present or after direct trauma from

## Pathologic Basis of Veterinary Disease, 4th Edition

catheterization. Urine in such cases is described as cloudy, flocculent, foul-smelling, and red-tinged. The mucosa can have foci of erosion or ulceration, patches or sheets of adherent exudate and necrotic debris, or adherent blood clots (Fig. 11-76, A).

Microscopically, acute cystitis is characterized by epithelial denudation with bacterial colonies present on the surface. The lamina propria is intensely edematous and has a diffuse neutrophilic infiltrate. Superficial hyperemia and hemorrhage are usually present (Fig. 11-76, B). A mild perivascular leukocytic infiltrate can occur in the tunica muscularis.

Clinically, dysuria, stranguria, and hematuria characterize acute onset of bacterial cystitis. An inflammatory sediment is detected on urinalysis, and bacteria can be grown in pure culture from urine samples.

Viral causes of acute cystitis are relatively rare in veterinary medicine. In cats a cell-associated herpesvirus has been found in some cases of mild cystitis. Hemorrhagic cystitis sometimes occurs in malignant catarrhal fever in cattle and deer and occasionally is the dominant gross feature in the disease.

Acute cystitis can result from several chemical causes. Active metabolites of cyclophosphamide, a drug used to treat neoplastic and immune-mediated diseases of dogs and cats, can cause a sterile hemorrhagic cystitis. Cantharidin toxicosis in horses results from ingestion of blister beetles (*Epicauta* sp.) in alfalfa hay, and hemorrhagic and necrotic cystitis develops from cantharidin excreted through the urinary tract. Chronic ingestion of bracken fern (*Pteridium aquilinum*) by cattle can result in the syndrome enzootic hematuria, which can be manifested as acute urinary bladder hemorrhage, chronic cystitis, or urinary bladder neoplasia.

### 11.3.3.2

#### CHRONIC CYSTITIS

Chronic cystitis presents as several forms based on the pattern and type of inflammatory response noted. These forms include diffuse, follicular, and polypoid variants. Diffuse variants reveal an irregularly reddened and usually thickened mucosa. There is some epithelial desquamation, and the submucosa is heavily infiltrated with mononuclear inflammatory cells; there are few neutrophils. In addition, there is often connective tissue thickening of the submucosa and hypertrophy of the muscularis layer.

Follicular variants reveal disseminated, nodular, submucosal lymphoid proliferations (2 to 4 mm in diameter) such that the mucosa has a cobblestone appearance (follicular cystitis) (Fig. 11-77). This response is particularly common when cystitis is associated with chronic urolithiasis. These white-gray lymphoid foci are often surrounded by a zone of hyperemia. Often, the lesions are a diffusely thickened, hyperplastic mucosa with goblet cell hyperplasia and a chronic lymphoplasmacytic infiltrate and fibrosis in the lamina propria. Hypertrophy of the tunica muscularis can be observed.

Polypoid masses (chronic polypoid cystitis), seen predominantly in female dogs, likely develops from inflammatory and hyperplastic responses secondary to chronic irritation, which most often arises from persistent bacterial urinary tract infection or uroliths. These hyperplastic transitional epithelial responses are called cystitis cystica, cystitis glandularis, and Brunn's epithelial nests. Inflammation, epithelial proliferation, and development of a nonneoplastic mass occur most typically in the cranioventral bladder wall. The mucosa has single or multiple, nodular mucosal masses (Fig. 11-78) composed of fibrous connective tissue and infiltrated with neutrophils and mononuclear leukocytes. The masses are broad-based or pedunculated, ulcerated, or covered by hyperplastic epithelium with goblet cell metaplasia. Chronic polypoid cystitis is characterized by clinical hematuria.

687

688

(Courtesy Dr. A. Confer, College of Veterinary Medicine, Oklahoma State University.)

### 11.3.3.3 MYCOTIC CYSTITIS

Mycotic cystitis is occasionally seen in domestic animals when opportunistic fungi, such as *Candida albicans* or *Aspergillus* sp., colonize the urinary bladder mucosa. Such fungal infections usually occur secondary to chronic bacterial cystitis, especially when animals are immunosuppressed or subjected to prolonged antibiotic therapy. Occasionally, blastomyces can produce lower urinary tract lesions in dogs. The urinary bladder is usually ulcerated with proliferation of underlying lamina propria; a generalized thickening of the urinary bladder wall is because of extensive inflammation consisting of neutrophils, lymphocytes, plasma cells, macrophages and edema, and fibrosis.

### 11.3.3.4 TOXIC CYSTITIS

There are rare proven veterinary examples of toxic cystitis (see Acute Cystitis). The most recognized is that of enzootic hematuria subsequent to ingestion of bracken fern.

#### 11.3.3.4.1 Enzootic Hematuria

Enzootic hematuria is a disease of cattle caused by chronic ingestion of bracken fern (*Pteridium aquilinum*). Bracken fern is a very common forage plant and one of the few to cause both cystitis and naturally occurring tumors in animals. There are two subspecies of bracken fern: *Pteridium aquilinum* ssp. *aquilinum*, containing eight varieties, and *Pteridium aquilinum* ssp. *caudatum*, containing four varieties, and it is not known whether all varieties are toxic. *Pteridium revolutum*, a species of bracken fern

## Pathologic Basis of Veterinary Disease, 4th Edition

---

common in south Asia, and *Pteridium esculentum*, a bracken fern of Australia, also produce enzootic hematuria. In areas where bracken does not grow, other ferns, such as the Australian *Cheilanthes sieberi* (mulga or rock fern) are capable of producing enzootic hematuria.

Bracken fern contains several toxic substances, including a thiaminase, a variety of carcinogens (quercetin, shikimic acid, prunasin, ptaquiloside [braxin C], ptaquiloside Z, aquilide A, and others), a “bleeding factor” of unknown structure, and substances that act as immunosuppressants. Following administration of ptaquiloside to guinea pigs, hemorrhagic cystitis results, suggesting that this is one of the toxic principles in bracken fern hematuria.

The extent and persistence with which toxic ferns are grazed probably influences the incidence of bladder lesions. Cattle fed low levels of bracken fern develop microscopic, followed by macroscopic, hematuria. Microhematuria usually is associated with petechial, ecchymotic, or suffusive hemorrhages in the urothelium of the renal calyces, pelvis, ureter, and bladder, and, microscopically, ectasia and engorgement of capillaries are present. Altered vessels are prone to hemorrhage into the bladder wall or lumen, and nodular hemangiomatous lesions develop in affected areas. In a few animals, macroscopic hematuria is due solely to these nonneoplastic changes, but usually it is caused by development of tumors, which ulcerate and bleed into the lumen.

A large proportion of neoplasms are located on the ventral and lateral walls of the bladder, which are in constant contact with urine, although occasionally tumors also develop in the renal pelvis and ureter. Epithelial neoplasms appear to develop from the hyperplastic and metaplastic (squamous and mucous) changes in the urothelium, which often accompany the vascular lesions described previously. Additionally, Brunn's nests (solid or branched clusters of epithelial cells occurring in the submucosa of the ureter) in the mucosa may act as the site of origin for these neoplasms. Chronic cystitis usually accompanies the neoplastic changes.

688

Several types of epithelial and mesenchymal neoplasms may develop, including: transitional cell carcinoma, squamous cell carcinoma, papilloma, adenoma, hemangioma, hemangiosarcoma, leiomyosarcoma, fibroma, and fibrosarcoma. Multiple tumors of more than one type may be present, and in more than 50% of affected cattle, mixed epithelial-mesenchymal neoplasms develop. Malignant types may invade locally, and about 10% of epithelial malignancies metastasize to the medial iliac nodes or lungs.

689

Uroplakins are products of urothelial cell differentiation, which form a major portion of the asymmetric unit membrane and are more consistently expressed in the superficial transitional epithelium. There was a decrease in superficial positive immunohistochemical uroplakin staining in increasingly malignant urothelial tumors in cattle. Although not necessarily of use in prognosticating tumors, staining for this molecule may assist identification of metastatic urothelial cell clusters, and further characterize transitional cell differentiation in neoplasia.

### 11.3.4 NEOPLASIA

Neoplasms of the lower urinary tract occur predominantly in the urinary bladder. They are observed most frequently in dogs, occasionally in cats, and rarely in other species. Urinary bladder neoplasms comprise less than 1% of total canine neoplasms. Most occur in old dogs, without a sex predisposition.

Risk factors associated with bladder cancer in dogs include the following:

1. Topical insecticides
2. Exposure to marshes sprayed with chemicals for mosquitos
3. Environments with high industrial activity
4. Female gender
5. Obesity
6. Breed (e.g., Scottish terrier)

Retention of urine in the bladder and longer exposure of the epithelium to carcinogens results in a higher incidence of tumors in the urinary bladder. Many chemicals, including intermediate components of aniline dyes, aromatic hydrocarbons, and tryptophan metabolites, have been found experimentally or epidemiologically to induce urinary bladder neoplasms. Chemically induced and spontaneous tumors progress through a series of histologic stages from hyperplasia, squamous metaplasia, dysplasia, carcinoma in situ, papilloma, adenoma, and carcinoma. Lower urinary tract neoplasms occupy space and often cause mucosal ulceration, resulting in clinical signs of dysuria, hematuria, or obstruction. Urinary bladder neoplasms can invade or block the ureters, causing obstruction of ureteral urine flow, increased ureteral pressure, and hydronephrosis.

### 11.3.4.1

#### EPITHELIAL TUMORS

Epithelial neoplasms are by far the most common to involve the urinary system and are classified as transitional cell papillomas, transitional cell carcinomas, squamous cell carcinomas, adenocarcinomas, and undifferentiated carcinomas.

1. Papillomas have a papilliferous or pedunculated appearance. Microscopically, they have a papillary growth pattern consisting of multiple papilliferous fibrous cores covered by well-differentiated transitional epithelium.
2. Carcinomas are focal, raised nodules or diffuse thickening of the urinary bladder wall, most common in the trigone region of the bladder ([Fig. 11-79, A](#)). Transitional cell carcinomas are composed of pleomorphic to anaplastic transitional epithelium. Neoplastic transitional cells cover the mucosal surface as irregular layers, readily invade the lamina propria in the form of solid nests and acini, and are found within lymphatic vessels of the submucosal and muscle layers ([Fig. 11-79, B](#)).
3. Squamous cell carcinomas, adenocarcinomas, and unclassified carcinomas most likely arise from transitional epithelium. In the bitch, carcinomas are multicentric in origin, develop not only in the urinary bladder but also in the urothelium of the ureters, urethra, and renal pelvis and often extend to the vagina and vestibule.

Metastasis of urinary bladder carcinomas is most often first seen in regional lymph nodes adjacent to the aortic bifurcation, including the deep inguinal, medial iliac, and sacral lymph nodes. Other potential sites of metastasis include lungs and kidneys, with metastasis to other parenchymatous organs occurring later.

### 11.3.4.2 MESENCHYMAL TUMORS

Mesenchymal tumors including fibromas, fibrosarcomas, leiomyomas, leiomyosarcomas, rhabdomyosarcomas, lymphosarcomas, hemangiomas, and hemangiosarcomas occur in the lower tract. Primary fibrosarcomas, leiomyosarcomas, hemangiomas, and hemangiosarcomas are rare.

1. Leiomyomas are the most common neoplasms and are solitary or multiple, circumscribed, firm, pale white to tan masses in the urinary bladder wall. Leiomyomas have the macroscopic consistency and microscopic appearance of normal smooth muscle.
2. Fibromas arise from lamina propria connective tissue and project into the bladder lumen as solitary nodules.
3. Lymphosarcoma occasionally infiltrates the wall, not only of the bladder but also of the ureters and renal pelves in cattle with malignant lymphoma.

689

4. Rhabdomyosarcomas are rare but occur in bladders and urethra of young large breed dogs (younger than 18 months old), suggesting an embryonal origin. The cell of origin is speculated to be embryonic myoblasts from the urogenital ridge. These masses are described as botryoid (grapelike) because they are large, fungating masses (4 to 18 cm in diameter) that protrude into the bladder lumen. Local invasion and occasional metastasis to lymph nodes characterize the typical behavior. Microscopically the neoplasms are composed of sheets of fusiform cells interspersed with pleomorphic cells. Microscopic demonstration of cross striations typical of skeletal muscle or immunohistochemical demonstration of the intermediate filament desmin are useful to confirm the diagnosis of rhabdomyosarcoma. Clinical presentation includes hematuria, urinary obstruction, hydroureter, hydronephrosis, and hypertrophic osteopathy.

690

**Fig. 11-79 Transitional cell carcinoma, urinary bladder, dog.** **A**, Transitional cell carcinomas are typically seen adjacent to the trigone (as here), where they can become large enough to obstruct the opening of a ureter or ureters and result in secondary hydroureter and/or hydronephrosis. **B**, Lamina propria. The tumor is anaplastic. Cells are grouped in small islands and clusters. Nuclei are vesicular with prominent nucleoli, and some nuclei show remarkable anisokaryosis. H&E stain. (**A**, Courtesy Dr. A. Confer, College of Veterinary Medicine, Oklahoma State University. **B**, Courtesy Dr. S.J. Newman, College of Veterinary Medicine, University of Tennessee.)

## 12 Chapter 12 Endocrine System

KRISTA M.D. LA PERLE

CHARLES C. CAPEN

### 12.1 INTRODUCTION

Endocrine glands are collections of specialized cells that synthesize, store, and directly release their secretions, such as polypeptides, steroids, and amino acid derivatives—including catecholamines and thyroid hormones—into the blood stream, resulting in physiologic effects on target cells distant from the glands. They are sensing and signaling devices located in the extracellular fluid compartment that are capable of responding to changes in the internal and external environments to coordinate a multiplicity of activities that maintain homeostasis.

Signaling molecules are grouped into three general categories according to the source of the signal and the location of the target on which the signal has an effect ([Fig. 12-1](#)). In autocrine signaling, cells respond to signals that they themselves secrete. Molecules produced by one cell that act on a neighboring cell are characteristic of paracrine signaling. The final pattern of signaling, which is the focus of this chapter, is endocrine signaling whereby hormones produced by cells of endocrine organs are released into the circulation and act on distant target cells.

Endocrine cells that produce polypeptide hormones have a well-developed, rough endoplasmic reticulum that assembles the hormone, and a prominent perinuclear Golgi apparatus that packages the hormone into granules for intracellular storage and transport. Secretory granules are unique to polypeptide hormone- and catecholamine-secreting endocrine cells and provide a mechanism for intracellular storage of substantial amounts of preformed active hormone. When the cell receives a signal to secrete a hormone, secretory granules are moved to the periphery of the endocrine cell, most likely by the contraction of microfilaments. Following release of the peptides into the blood stream, they bind to receptors on the surface of target cells, activating a series of intracellular events often mediated by second messengers such as cyclic adenosine monophosphate (cAMP), protein kinases, or calcium.

Steroid hormone-secreting cells are characterized by large cytoplasmic lipid bodies that contain cholesterol and other precursor molecules. The lipid bodies are in close proximity to an extensive smooth endoplasmic reticulum and large mitochondria. The latter have hydroxylase and dehydrogenase enzyme systems that attach various side chains to the basic steroid nucleus. Steroid-producing cells lack secretory granules and do not store significant amounts of preformed hormone. They depend on continued biosynthesis to maintain the normal secretory rate of a particular hormone. Steroid hormones enter target cells by diffusion across the plasma membrane and then bind to nuclear or cytosolic receptors.

#### 12.1.1 STRUCTURE AND FUNCTION

In general, endocrine organs are composed of islands of secretory epithelial cells delineated by a fine fibrovascular stroma, which is rich in capillaries. With the exception of thyroid follicular epithelial cells, endocrine cells are arranged in cords or packets. Endocrine cells that secrete polypeptide hormones and catecholamines typically contain abundant, lacy to finely granular, pale eosinophilic cytoplasm, which is immunoreactive for chromogranins and synaptophysin that are present in secretory granules and microvesicles,

## Pathologic Basis of Veterinary Disease, 4th Edition

respectively. Steroid hormone-secreting endocrine cells also contain abundant cytoplasm that appears foamy because of the presence of abundant lipid vacuoles.

### 12.1.1.1 PITUITARY GLAND (HYPOPHYSIS)

The adenohypophysis consists of three portions: the pars distalis, pars tuberalis, and pars intermedia (Fig. 12-2). In many animal species, the adenohypophysis completely surrounds the pars nervosa of the neurohypophyseal system. The pars distalis is the largest and is composed of several different endocrine cell populations that secrete pituitary trophic hormones (Fig. 12-3). The secretory cells are surrounded by abundant capillaries.

693

694

Fig. 12-1 Schematic diagram of the patterns of intercellular signaling (see text). (Modified from Lodish H, Baltimore D, Berk A et al, editors: *Molecular cell biology*, ed 3, New York, 1995, WH Freeman, with permission.)

## Pathologic Basis of Veterinary Disease, 4th Edition

The pars tuberalis is an extension of the adenohypophysis and consists of dorsal projections of parenchymal cells along the infundibular stalk. It primarily functions as a scaffold for the capillary network of the hypophyseal portal system as it courses from the median eminence to the pars distalis. The pars intermedia is located between the pars distalis and pars nervosa; it lines the residual lumen of Rathke's pouch and has two populations of cells in certain species. In the dog, one of these cell types (B cell) synthesizes and secretes adrenocorticotrophic hormone (ACTH).

A specific population of endocrine cells is present in the pars distalis (and also in the pars intermedia of dogs for ACTH secretion) that synthesizes, processes, and secretes each of the pituitary trophic hormones (Fig. 12-4). Secretory cells in the adenohypophysis are classified as acidophils, basophils, and chromophobes based on the reactions of their secretory granules with pH-dependent histochemical stains. Based on contemporary specific immunohistochemical staining, acidophils can be further subclassified functionally into somatotrophs that secrete growth hormone (GH; somatotrophin), lactotrophs that secrete prolactin and ACTH-secreting corticotrophs. Their granules contain simple protein hormones. Basophils include both gonadotrophs that secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH) and thyrotrophs that secrete thyrotrophic hormone (thyroid-stimulating hormone [TSH]). Chromophobes are pituitary cells that by light microscopy lack stainable cytoplasmic secretory granules. They include the pituitary cells involved with the synthesis of ACTH and melanocyte-stimulating hormone (MSH) in some species, nonsecretory follicular (stellate) cells (Fig. 12-3), degranulated chromophils (acidophils and basophils) in the actively synthesizing phase of the secretory cycle, and undifferentiated stem cells of the adenohypophysis.

Capen, College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Each type of endocrine cell in the adenohypophysis is under the control of a specific releasing hormone or factor from the hypothalamus (Fig. 12-4). These releasing hormones are small peptides synthesized and secreted by neurons of the hypothalamus. They are transported by axonal processes to the median eminence, where they are released into capillaries and conveyed by the hypophyseal portal system to specific endocrine cells in the adenohypophysis. Each hormone stimulates the rapid release of secretory granules containing a specific preformed trophic hormone.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The neurohypophysis is subdivided into three anatomic parts. The pars nervosa (posterior lobe) represents the distal component of the neurohypophyseal system. The infundibular stalk joins the pars nervosa to the overlying hypothalamus and is composed of axonal processes from neurosecretory neurons. It also has numerous capillaries, supported by modified glial cells or pituicytes, which are termination sites for the nonmyelinated axonal processes of neurosecretory neurons in the hypothalamus. The neurohypophyseal hormones, oxytocin and antidiuretic hormone (ADH) or vasopressin, are synthesized in the cell body of hypothalamic neurons, packaged into secretory granules, transported by long axonal processes of the hypothalamo-hypophyseal tract to axons in the pars nervosa, and released into the capillary bed of the hypothalamohypophysial portal system (Fig. 12-4).

Neurosecretory neurons in the hypothalamus secrete hormone in response to neural input from higher centers, resulting in hormonal secretion. ADH and oxytocin are nonapeptides synthesized by neurons situated either in the supraoptic or paraventricular nuclei of the hypothalamus. ADH and its corresponding neurophysin appear to be synthesized as part of a common larger biosynthetic precursor molecule, termed propressophysin. The hormones are packaged with a corresponding binding protein (i.e., neurophysin) into membrane-limited neurosecretory granules and transported to the pars nervosa for release into the circulation.

### 12.1.1.2 ADRENAL GLAND

#### 12.1.1.2.1 Adrenal Cortex

The adrenal glands of mammals consist of two distinct parts that differ not only in morphology and function but also in embryologic origin. Because of their close structural relationships, the outer cortex and inner medulla of the adrenal glands usually have been considered parts of one organ. The adrenal cortex develops from cells of the coelomic epithelium that are of mesodermal origin. The chromaffin tissue and sympathetic ganglion cells of the adrenal medulla are derived from ectoderm of the neural crest.

The adrenal cortex of normal dogs is firm, yellow, and of nearly uniform thickness. The soft, brown medulla is surrounded by the cortex. In normal dogs the cortical-to-medullary ratio is approximately 2:1. The adrenal glands are richly vascularized, and a sinusoidal network, which demarcates the cell columns of the adrenal cortex, empties into the venous tree at the periphery of the medulla.

The adrenal cortex microscopically and functionally is subdivided into three layers or zones, although the demarcation between zones often is not distinct. The zona glomerulosa or multiformis (outer zone) adjacent to the capsule is composed of columns of cells that have a sigmoid or arclike arrangement. It represents about 15% of the cortical volume and is responsible for the secretion of mineralocorticoid hormones. The secretory cells of the zona fasciculata (middle zone) are arranged in long anastomosing cords separated by numerous small capillaries. This zone constitutes about 80% of the cortical volume, is composed of cells that contain abundant cytoplasmic lipid, and is responsible for the secretion of the glucocorticoid hormones. The zona reticularis (inner zone) accounts for the remaining 5% of the cortical volume. The secretory cells, arranged in small groups surrounded by capillaries, are responsible for the secretion of sex steroids.

Mineralocorticoids are adrenal steroids that principally affect ion transport by epithelial cells and cause excretion of potassium and conservation of sodium. The most potent and important naturally occurring mineralocorticoid is aldosterone. Enzymatically controlled electrolyte pumps in epithelial cells of the renal tubule and sweat glands respond to mineralocorticoids by conserving sodium and chloride and by

695

697

## Pathologic Basis of Veterinary Disease, 4th Edition

excreting potassium. In the distal convoluted tubule of the mammalian nephron, a cation-exchange mechanism is responsible for the resorption of sodium from the glomerular filtrate and secretion of potassium into the lumen (Fig. 12-5). These reactions are accelerated by mineralocorticoids but still proceed, although at a much slower rate in their absence. Lack of mineralocorticoid secretion, such as in the Addison's-like disease of dogs, can result in lethal retention of potassium and loss of sodium.

**Fig. 12-4 Hypothalamic-pituitary-target gland axis.** Releasing hormones produced by the hypothalamus act on anterior or posterior portions of the pituitary gland to release trophic hormones. Trophic hormones act on specific endocrine glands, stimulating them to produce hormones that exert ultimate actions on downstream tissues. *CRH*, Corticotropin-releasing hormone; *FSH*, follicle-stimulating hormone; *GHIH*, growth hormone-inhibiting hormone; *GHRH*, growth hormone-releasing hormone; *GnRH*, gonadotropin-releasing hormone; *LH*, luteinizing hormone; *PRH*, prolactin-releasing hormone; *PRIF*, prolactin release-inhibiting factor; *TRH*, thyrotropin-releasing hormone. ## Pathologic Basis of Veterinary Disease, 4th Edition

Cortisol and lesser amounts of corticosterone are the most important naturally occurring glucocorticoid hormones secreted by the adrenal glands in many animal species. In general, the actions of glucocorticoids on carbohydrate, protein, and lipid metabolism result in sparing of glucose, a tendency to hyperglycemia, and increased glucose production. In addition, glucocorticoids decrease lipogenesis and increase lipolysis in adipose tissue, which results in release of glycerol and free fatty acids.

Glucocorticoids also function to suppress both inflammatory and immunologic responses, thereby reducing the necrosis and fibroplasias that can occur with these responses. However, under the influence of increased concentrations of glucocorticoids, an animal has reduced resistance to bacteria, viruses, and fungi. Glucocorticoids can impair the immunologic response at any stage from the initial interaction and processing of antigens by cells of the monocyte-macrophage system through the induction and proliferation of immunocompetent lymphocytes and subsequent antibody production. Inhibition of a number of functions of lymphoid cells by glucocorticoids forms part of the basis for immunosuppression.

**Fig. 12-5 Aldosterone secreted by the zona glomerulosa of the adrenal cortex acts on the distal portions of the nephron to increase tubular excretion of potassium and increase resorption of sodium (and secondarily of chloride).** The resulting osmotic gradient facilitates movement of water from the glomerular filtrate into the extracellular fluid (ECF). (Redrawn with permission from Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

Glucocorticoids exert a profound negative effect on wound healing. Dogs with hypercortisolism can have wound dehiscence (Fig. 12-6). The basic mechanism is inhibition of fibroblast proliferation and collagen synthesis, leading to a decrease in scar tissue formation.

Sex hormones (e.g., progesterone, estrogens, and androgens) are synthesized in small amounts by secretory cells of the zona reticularis of the adrenal cortex. Excessive adrenal sex steroids secreted by a neoplasm arising in the zona reticularis can occur infrequently, resulting in clinical manifestations of virilism, precocious sexual development, or feminization (effects depend on which steroid is secreted in excess, the sex of the patient, and the age at onset).

## Pathologic Basis of Veterinary Disease, 4th Edition

12.1.1.2.2

### Adrenal Medulla

The adrenal medulla is derived from neuroectoderm of the neural crest and produces catecholamine hormones. The main biosynthetic pathway for catecholamines in mammals starts with tyrosine that is converted first to 1-dihydroxyphenylalanine (dopa) by tyrosine hydroxylase. Dopa is then decarboxylated by 3,4-amino acid decarboxylase to 3,4-dihydroxyphenylethylamine (dopamine), which subsequently undergoes  $\beta$ -hydroxylation by dopamine  $\beta$ -oxidase to form norepinephrine. In mammals the medulla is completely surrounded by the adrenal cortex, and venous blood from the cortex bathes the medullary cells. This blood has the greatest concentration of corticosteroids of any fluid in the body. This close anatomic association between the adrenal cortex and medulla in mammals is not fortuitous because the *N*-methylating enzyme, phenylethanolamine-*N*-methyl transferase, which converts norepinephrine to epinephrine, is corticosteroid hormone dependent.

697

### 12.1.1.3 THYROID GLAND

#### 12.1.1.3.1 Thyroid Follicular Cells

The thyroid gland in most animal species has two lobes, one on each lateral surface of the trachea. In pigs, the main lobe of the thyroid gland is on the midline in the ventral cervical region with dorsolateral projections from each side. In dogs, the right lobe of the thyroid gland is situated slightly cranial to the left lobe and almost touches the caudal aspect of the larynx.

The thyroid gland is the largest of the endocrine organs that function exclusively as endocrine glands. The basic histologic structure of the thyroid gland is unique among endocrine glands and consists of follicles of varying size (20 to 250  $\mu\text{m}$ ), which contain colloid produced by the follicular cells. The follicular cells are cuboidal to columnar and are orientated so that their secretory pole is directed toward the lumen of the follicle. An extensive network of interfollicular and intrafollicular capillaries provides the follicular cells with an abundant blood supply. Follicular cells have extensive profiles of rough endoplasmic reticulum for synthesis and a large Golgi apparatus for packaging of substantial amounts of protein, which are then transported into the follicular lumen. The luminal side of follicular cells in contact with the colloid has numerous microvilli (Fig. 12-7).

The synthesis of thyroid hormones is unique among those of the endocrine glands because the final assembly of hormone occurs extracellularly within the follicular lumen. Follicular cells trap essential raw materials, such as iodide from the blood, by a sodium-iodide symporter in the basolateral plasma membrane and then transport them rapidly against a concentration gradient to the lumen, where the iodide is oxidized by thyroperoxidase in the microvilli to iodine ( $\text{I}_2$ ) (Fig. 12-8). The assembly of thyroid hormones within the follicular lumen is made possible by a unique protein, thyroglobulin. Thyroglobulin is a high molecular weight (600,000 to 750,000 Da) glycoprotein synthesized in successive subunits on the ribosomes of the endoplasmic reticulum in follicular cells. The constituent amino acids (tyrosine and others) and carbohydrates (e.g., mannose, fructose, galactose) are derived from the circulation. Recently synthesized thyroglobulin (17S) leaves the Golgi apparatus and is packaged into apical vesicles that are extruded into the follicular lumen (Fig. 12-8). The amino acid tyrosine, an essential component of thyroid hormones, is incorporated within the molecular structure of thyroglobulin. Iodine is bound to tyrosyl residues in thyroglobulin at the apical surface of follicular cells to form moniodotyrosine (MIT) and diiodotyrosine (DIT) (Fig. 12-8). The resulting MIT and DIT combine to form the two biologically active iodothyronines,  $\text{T}_4$  and  $\text{T}_3$ , secreted by the thyroid gland.

**Fig. 12-7 Thyroid follicular cells, thyroid gland, normal dog.** Thyroid follicular cells with long microvilli (V) that extend into the colloid (C) within the follicular lumen. Numerous lysosomes (L) and colloid droplets (CD) are present in the apical portion of the follicular cells. An interfollicular capillary (arrow) is present at the base of the follicle. TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

The secretion of thyroid hormones into the blood stream from colloid is initiated by elongation of microvilli and formation of pseudopodia on the luminal surface of follicular cells. In response to TSH, these extend into the follicular lumen, and indiscriminately phagocytose the adjacent colloid. Colloid droplets within follicular cells fuse with numerous lysosomes.  $T_3$  and  $T_4$  are released from the thyroglobulin molecule, diffuse across the follicular cell basement membrane, and enter into adjacent capillaries. Negative feedback control of thyroid hormone secretion is accomplished by the coordinated response of the adenohypophysis and certain hypothalamic nuclei to concentrations of  $T_4$  and  $T_3$  in the blood.

TSH is delivered to thyroid follicular cells where it binds to the basilar aspect of the cell, activates adenyl cyclase, and increases the rate of all biochemical reactions concerned with the biosynthesis and secretion of thyroidal hormones. If the secretion of TSH is sustained (hours or days), thyroid follicular cells become more columnar and follicular lumina become smaller as a result of increased uptake of colloid by endocytosis (Fig. 12-9). Numerous periodic acid-Schiff (PAS)-positive colloid droplets are present in the luminal aspect of the hypertrophied follicular cells. The converse occurs in the thyroid gland in response to increases in circulating  $T_4$  and  $T_3$ , which cause a corresponding decrease in TSH. Thyroid follicles become enlarged and distended with colloid as a result of decreased TSH-mediated endocytosis of colloid. Follicular cells lining the involuted follicles become low cuboidal, with only a few endocytic vacuoles at the interface between the colloid and follicular cells (Fig. 12-10).

698

699

**Fig. 12-8 Thyroid follicular cells illustrating two-way traffic of materials from capillaries into the follicular lumen.** Raw materials, such as iodine, are concentrated by follicular cells and rapidly transported into the lumen (*left side of drawing*). Amino acids (tyrosine and others) and sugars are assembled by follicular cells into thyroglobulin (Thg), packaged into apical vesicles (AV) and released into the lumen. The iodination of tyrosyl residues with the thyroglobulin molecule to form thyroid hormones occurs within the follicular lumen. Elongation of microvilli (MV) and endocytosis of colloid (Co) by follicular cells occur in response to thyroid-stimulating hormone (TSH) stimulation (*right side of drawing*). The intracellular colloid droplets (CD) fuse with lysosomal bodies (Ly), active thyroid hormone is enzymatically cleaved from thyroglobulin, and free  $T_4$  and  $T_3$  are released into the circulation. $T_4$  and  $T_3$ , once released into the circulation, act on many different target cells in the body. The overall functions of  $T_4$  and  $T_3$  are similar, although much of the biologic activity appears to be the result of monodeiodination of  $T_4$  to 3,5,3'-triiodothyronine ( $T_3$ ) before they interact with high-affinity nuclear receptors in target cells. In certain conditions such as protein starvation during the neonatal period, hepatic and renal disease, and fever,  $T_4$  is preferentially monodeiodinated to 3,3',5'-triiodothyronine (reverse  $T_3$ ). Because reverse  $T_3$  produced by target cells is biologically inactive, monodeiodination to form reverse  $T_3$  provides a mechanism by which the overall metabolic effects of thyroid hormones are attenuated. The subcellular mechanism of action of thyroid hormones resembles that of steroids, in that free hormone enters target cells and binds initially to cytosol-binding proteins and subsequently to high-affinity nuclear receptors. Binding of thyroid hormone to receptors on the inner mitochondrial membrane is responsible for the early activation of energy metabolism and increased oxidative phosphorylation.

12.1.1.3.2

### Thyroid C (Parafollicular) Cells

Calcitonin is secreted by a second endocrine cell population, C or parafollicular cells, in the mammalian thyroid gland. These cells are situated either in the follicular wall, within the basement membrane between follicular cells (Fig. 12-11), or in small groups adjacent to interfollicular capillaries between follicles. C cells do not border the follicular colloid directly, and their secretory pole is oriented toward the interfollicular capillaries. The distinctive feature of C cells is the presence of numerous small, membrane-limited secretory granules in their cytoplasm (Fig. 12-11). Immunohistochemical techniques have demonstrated calcitonin activity in these secretory granules.

**Fig. 12-11 Thyroid C cell, thyroid gland, normal dog.** Thyroid C (parafollicular) cell with numerous secretory granules (S) and moderate development of Golgi apparatus and rough endoplasmic reticulum. Microvilli from follicular cells (arrow) extend into the colloid of the follicular lumen (C). Capen, College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Calcitonin is a polypeptide hormone, and the calcium ion concentration in plasma and extracellular fluids is the principal physiologic stimulus for the secretion of calcitonin by C cells. The rate of secretion of calcitonin is increased greatly in response to increased blood calcium concentrations.

C cells store substantial amounts of calcitonin in their cytoplasm, and the hormone is discharged rapidly into interfollicular capillaries in response to hypercalcemia (Fig. 12-12). C cells respond to long-term hypercalcemia by hyperplasia. When the blood calcium concentration is reduced, the stimulus for calcitonin secretion is diminished, and numerous secretory granules accumulate in the cytoplasm of C cells (Fig. 12-12). Calcitonin exerts its function by interacting with target cells located primarily in bone and kidneys. The actions of parathyroid hormone (PTH) and calcitonin are antagonistic on bone resorption, but synergistic in decreasing the renal tubular reabsorption of phosphorus.

### 12.1.1.4 PARATHYROID GLANDS

Parathyroid glands in most animal species consist of two pairs of glands situated in the cranial cervical region. The dog and cat have both external and internal parathyroid glands located near the thyroid gland. Other animal species, such as the pig and laboratory rat, have only a single pair of parathyroid glands cranial to the thyroid gland, embedded either in the thymus in young animals or in adipose connective tissue in adult animals. In cattle and sheep, the larger external parathyroid gland is located a considerable distance cranial to the thyroid gland in the loose connective tissue along the common carotid artery. The smaller internal parathyroid glands are situated on the dorsal and medial surface of the thyroid gland. In horses, the larger (“lower”) parathyroid gland is located a considerable distance from the thyroid gland in the caudal cervical region, near the bifurcation of the bicarotid trunk at the level of the first rib, whereas the smaller (“upper”) parathyroid gland is situated near the thyroid gland.

The parathyroid glands of animals and human beings are composed predominantly of chief cells in different stages of secretory activity or in transition to oxyphilic cells in certain species. Oxyphilic cells increase in number with advancing age and often form nodules in the parathyroid glands of aged animals. They are larger than chief cells, and their abundant cytoplasm is filled with numerous large, often bizarre-shaped mitochondria.

Biologically active PTH secreted by chief cells is a straight-chain polypeptide consisting of 84 amino acid residues, with a molecular weight of approximately 9500 Da. Secretory cells in the parathyroid glands of most animals store relatively small amounts of preformed hormone but are capable of responding to minor fluctuations in calcium ion concentration rapidly by altering the rate of hormonal secretion and, more slowly, by altering the rate of hormonal synthesis (Fig. 12-13). In contrast to most endocrine organs, which are under complex control, the parathyroid glands have a unique feedback control system based primarily on the concentration of calcium and, to a lesser extent, of magnesium ions in blood. Calcium ion concentration controls not only the rate of biosynthesis and secretion of PTH but also other metabolic and intracellular degradative processes within chief cells. Increased calcium ion concentration in extracellular fluids rapidly inhibits the uptake of amino acids by chief cells, and consequently synthesis of proPTH, its conversion to PTH, and secretion of stored PTH (Fig. 12-13).	700 701 701 702
--	--------------------------

**Fig. 12-12 Response of thyroid C cells and parathyroid chief cells to hypercalcemia and hypocalcemia.** C cells accumulate secretory granules in response to hypocalcemia, whereas chief cells are nearly degranulated but have an increased development of synthetic and secretory organelles. In response to hypercalcemia, C cells are degranulated and parathyroid chief cells are predominantly in the inactive stage of the secretory cycle.  
(Redrawn with permission from Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

**Fig. 12-13 Bypass secretion of parathyroid hormone (PTH) in response to increased demand signaled by decreased blood calcium ion concentration.** Recently synthesized and processed active PTH can be released directly and not enter the storage pool of mature ("old") secretory granules in the cytoplasm of chief cells. PTH from the storage pool can be mobilized by cyclic adenosine monophosphate (cAMP) and  $\beta$ -agonists (such as epinephrine, norepinephrine, and isoproterenol) and by lowered blood calcium ion, whereas secretion from the pool of recently synthesized PTH can be stimulated only by a decreased calcium ion concentration. RER, Rough endoplasmic reticulum; GA, Golgi apparatus. (Redrawn with permission from Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

PTH is the principal hormone involved in the minute-to-minute, fine regulation of blood calcium concentration (total and ionic calcium) in mammals. It does this by directly influencing the function of target cells located primarily in bone and the kidneys, and indirectly acting in the intestine to maintain plasma calcium concentration sufficient to ensure the optimal functioning of a wide variety of body cells. The overall action of PTH on bone is to mobilize calcium into extracellular fluids (Fig. 12-14). Bone responds to PTH by increasing the activity of osteoclasts and osteocytes existing in bone.

PTH has a rapid (within 5 to 10 minutes) and direct effect on renal tubular function, leading to decreased reabsorption of phosphorus and consequently the development of phosphaturia. The site of action where PTH blocks tubular reabsorption of phosphorus has been determined to be the proximal tubule. The ability of PTH to enhance the renal absorption of calcium also is of considerable importance in the maintenance of calcium homeostasis. This effect of PTH on tubular reabsorption of calcium appears to be a result of a direct action on the distal convoluted tubule. Calcitonin and PTH, acting in concert, provide a dual negative

## Pathologic Basis of Veterinary Disease, 4th Edition

feedback control mechanism to maintain the concentration of calcium in extracellular fluids within narrow limits.

Fig. 12-14 Interrelation of parathyroid hormone (PTH), calcitonin (CT), and 1,25-dihydroxycholecalciferol ( $1,25\text{-[OH]}_2\text{VD}_3$ ) in hormonal regulation of calcium and phosphorus in extracellular fluids (ECF) (Redrawn with permission from Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

The third major hormone involved in the regulation of calcium metabolism and skeletal remodeling is cholecalciferol or vitamin  $\text{D}_3$  (Fig. 12-14). Cholecalciferol is ingested in small amounts in the diet and can be synthesized in the epidermis from precursor molecules (e.g., 7-dehydrocholesterol) through a provitamin  $\text{D}_3$  intermediate form in response to ultraviolet light. The active metabolites of vitamin D increase the absorption of calcium and phosphorus from the intestine and thereby maintain adequate concentrations of these electrolytes in the extracellular fluids as required for the appropriate mineralization of bone matrix. From a functional point of view, vitamin D brings about the retention of sufficient mineral ions to ensure mineralization of bone matrix, whereas PTH maintains the proper ratio of calcium to phosphorus in extracellular fluids. The major target tissue for  $1,25\text{-(OH)}_2\text{D}_3$  is the mucosa of the small intestine, where it increases the active transcellular transport of calcium (cranial small intestine) and phosphorus (caudal small intestine).

### 12.1.1.5

#### PANCREATIC ISLETS

The endocrine function of the pancreas is performed by small groups of cells, the islets of Langerhans (Fig. 12-15), which are completely surrounded by acinar or exocrine cells that produce digestive enzymes. During embryonic development of the pancreas, a close relationship exists between the endocrine and exocrine

## Pathologic Basis of Veterinary Disease, 4th Edition

portions. Evidence suggests that islet, acinar, and ductal cells arise from a common multipotential precursor cell. In early embryonic development, the endocrine cells are integrated within the exocrine matrix of the pancreatic bud. They subsequently accumulate in nonvascularized clusters and later become separated from the exocrine tissue and then independently vascularized.

702

703

**Fig. 12-15 Pancreatic islet, normal dog.** Gomori's aldehyde fuchsin stains the centrally located  $\beta$  cells (**B**) surrounded by a thin rim of poorly staining  $\alpha$  cells and  $\delta$  cells (**arrow**) at the periphery. The islets are surrounded by the exocrine pancreas. Gomori's aldehyde fuchsin. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

The pancreatic islets of normal animals contain multiple types of cells.  $\beta$  Cells, the predominant secretory cell, function in the biosynthesis of insulin but co-secrete islet amyloid polypeptide. The glucagon-secreting  $\alpha$  cells are less numerous than  $\beta$  cells.  $\delta$  Cells and F or PP cells in the islets secrete somatostatin and pancreatic polypeptide, respectively. The different cell types of the endocrine pancreatic cells can be differentiated by cytochemical (Fig. 12-15) and immunohistochemical techniques, and by electron microscopy (Fig. 12-16). The  $\alpha$ ,  $\beta$ , and  $\delta$  cells have well-developed rough endoplasmic reticulum and Golgi complexes that participate in the biosynthesis of polypeptide hormones, as well as numerous secretory granules in the cytoplasm. Each type of endocrine cell in the pancreatic islets has secretory granules with distinct morphologic characteristics, which can be used to identify the cell types (Fig. 12-16); however, immunohistochemical identification of the specific islet hormone is a more accurate method of identifying different cell types in the pancreatic islets.

The major physiologic stimulus for the release of insulin from  $\beta$  cells is glucose. An appropriate concentration of calcium ion in extracellular fluids is required for induction of insulin release from  $\beta$  cells. Insulin is a powerful hormone that has broad biologic influences and affects either directly or indirectly the structure and function of every organ in the body. Tissues especially responsive to insulin include skeletal

## Pathologic Basis of Veterinary Disease, 4th Edition

and cardiac muscle, adipose tissue, fibroblasts, hepatocytes, leukocytes, mammary glands, cartilage, bone, skin, aorta, pituitary gland, and peripheral nerves. The principal function of insulin is to stimulate anabolic reactions involving carbohydrates, lipids, proteins, and nucleic acids. It catalyzes the formation of macromolecules used in cell structure, energy stores, and regulation of many cell functions. Hepatocytes, adipose cells, and muscle are three principal target sites for insulin. In general, insulin increases the transfer of glucose and certain other monosaccharides, some amino acids and fatty acids, and potassium and magnesium ions across the plasma membrane of target cells. In addition, it enhances glucose oxidation and glycogenesis, and stimulates lipogenesis and the formation of adenosine triphosphate, DNA, and RNA. Insulin also decreases the rate of lipolysis, proteolysis, ketogenesis, and gluconeogenesis.

**Fig. 12-16 Pancreatic islet, normal dog.** Differences in secretion granules between  $\beta$  cells (B) and  $\alpha$  cells (A); the internal cores of secretion granules in  $\beta$  cells (arrowheads) are bar- or Y-shaped, with a prominent space between the limiting membrane and internal core. Secretion granules of the glucagon-secreting  $\alpha$  cells have an electron-dense, circular, internal core with a narrow submembranous space (arrow). TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

Glucagon is a hormone that stimulates energy release from target cells and is secreted in response to a reduction in blood glucose concentration. It mobilizes stores of energy-yielding nutrients by increasing glycogenolysis, gluconeogenesis, and lipolysis, thereby increasing the blood concentration of glucose. At physiologic concentrations, glucagon increases both hepatic glycogenolysis and gluconeogenesis. Insulin and glucagon act in concert to maintain the concentration of glucose in extracellular fluids within relatively narrow limits. A glucose sensor in the pancreatic islets controls the relative proportion of these two biologic antagonists. Glucagon controls glucose influx into the extracellular space from the hepatocytes, and insulin controls glucose efflux from the extracellular space into such insulin-sensitive cells as adipocytes, myocytes, and hepatocytes.

### 12.1.1.6 PINEAL GLAND

The pineal gland is a neuroendocrine organ which influences circadian rhythm and is intimately associated with the brain. It is composed of loose neuroglial stroma containing nests of pinealocytes and scattered calcified bodies known as brain sand or corpora arenacea. Pinealocytes secrete the hormonelike compound melatonin during periods of darkness. In addition to its role in circadian rhythms, melatonin is thought to influence seasonal reproductive activity in mammals through inhibition of gonadotropin-releasing hormone (GnRH).

### 12.1.1.7 CHEMORECEPTOR ORGANS

Chemoreceptor tissue is present at several sites in the body, including the carotid body, aortic bodies, nodose ganglion of the vagus nerve, ciliary ganglion in the orbit, pancreas, bodies on the internal jugular vein below the middle ear, and glomus jugular along the recurrent branch of the glossopharyngeal nerve. The chemoreceptor organs are sensitive indicators of changes in the blood carbon dioxide content, pH, and oxygen tension, thereby aiding in the regulation of respiration and circulation. Carotid and aortic bodies can initiate an increase in the depth, minute volume, and rate of respiration via parasympathetic nerves, and an increase in heart rate and elevation of arterial blood pressure via the sympathetic nervous system. The bodies are composed of parenchymal (chemoreceptor) cells and stellate (sustentacular) cells. Nerve endings with synaptic vesicles as well as nerve fibers occur in close association with the chemoreceptor cells.

### 12.1.2 PORTALS OF ENTRY

The portals of entry for the inflammatory agents affecting endocrine glands include hematogenous spread and direct extension. Autoimmune and infectious inflammatory diseases affect various endocrine glands. The pathogenesis of autoimmune diseases typically involves autoreactive T lymphocytes and autoantibodies, both of which gain access to the endocrine gland via the blood. Bacterial, viral, and fungal diseases preferentially restricted to individual endocrine glands rarely occur; however, endocrine glands are equally vulnerable to involvement in systemic diseases. Endocrine glands, such as the pituitary and pineal glands and the thyroid and parathyroid glands, can also become secondarily involved through direct extension from the meninges and larynx, respectively.

The endocrine system is unique in the fact that many of the disease processes affecting it involve disturbances of growth, such as hyperplasia and neoplasia. The histopathologic differentiation among nodular hyperplasia, adenoma, and carcinoma is often more difficult in endocrine glands than in most other organs of the body. However, criteria used to differentiate these proliferative lesions should be established and applied in a uniform manner in the evaluation of proliferative lesions in endocrine glands. For many endocrine glands (especially thyroid C cells, secretory cells of the adrenal medulla, thyroid follicular cells, parathyroid chief cells, endocrine cells of the pancreas, and specific trophic hormone-secreting cells of the adenohypophysis), there appears to be a continuous spectrum of proliferative lesions derived from a specific population of secretory cells between focal or nodular hyperplasia and adenomas.

Excessive focal growth of endocrine cells is the consequence of aberrant secretion of growth- and/or function-stimulating hormone(s) and has been referred to as nonneoplastic endocrine hyperplasia. Nodules arising in hyperplastic endocrine glands can be polyclonal and of clonal origin. Hyperfunction and cellular hypertrophy due to nonneoplastic endocrine hyperplasia are considered to be largely reversible upon cessation

## Pathologic Basis of Veterinary Disease, 4th Edition

---

of the inciting stimulus; however, chronic and severe hyperplasia of endocrine tissues is not always fully reversible.

Endocrine glands, especially in laboratory rodents, appear predisposed to the development of an increased incidence of neoplasms following prolonged stimulation of a population of secretory cells. Long-continued stimulation can lead to the development of clones of cells within the hyperplastic endocrine glands that grow more rapidly than the remainder and are consequently more susceptible to genetic alterations, which can result in neoplastic transformation when exposed to the right combination of promoting agents.

### 12.1.3 DEFENSE MECHANISMS

The primary defense mechanism employed by the endocrine system is the hierarchy of hormonal regulation known as the hypothalamic-pituitary-target gland axis (Fig. 12-4). The hypothalamus produces a number of releasing and inhibitory hormones in response to sensory input from the central nervous system (CNS). These releasing and inhibitory hormones act on anterior or posterior portions of the pituitary gland to stimulate or prevent the release of trophic hormones. Trophic hormones act on specific endocrine glands, stimulating them to produce hormones that exert ultimate actions on downstream tissues. Under normal circumstances, the action of a hormone is self-limiting because of the existence of negative feedback loops for each hormone series in which secretion of a particular hormone ultimately leads to inhibition of its subsequent secretion. Negative feedback from target endocrine glands can be directed at the hypothalamus, the pituitary gland, or both.

704

705

### 12.1.4 PATHOGENIC MECHANISMS OF ENDOCRINE DISEASES

Many diseases of endocrine glands are characterized by dramatic functional disturbances and characteristic clinicopathologic alterations affecting one or more body systems. The affected animal can have changes primarily involving the skin (alopecia caused by hypothyroidism), nervous system (seizures caused by hyperinsulinism), urinary system (polyuria caused by diabetes mellitus, diabetes insipidus, and hyperadrenocorticism), or skeletal system (fractures induced by hyperparathyroidism). There are several mechanisms that can disrupt normal endocrine function, with the majority of processes resulting in insufficient or excessive hormone production.

#### 12.1.4.1 PRIMARY HYPOFUNCTION OF AN ENDOCRINE GLAND

Hormone secretion is subnormal because of extensive destruction of secretory cells by a disease process, the failure of an endocrine gland to develop properly, or the result of a specific biochemical defect in the synthetic pathway of a hormone. In animals, immune-mediated injury causes hypofunction of several endocrine glands, including the adrenal cortex, thyroid gland, parathyroid glands, and pancreatic islets. Thyroiditis caused by this mechanism is characterized by notable infiltration of lymphocytes and plasma cells and deposition of electron-dense immune complexes along the follicular basement membranes with subsequent progressive destruction of secretory parenchyma.

Failure of development also results in primary hypofunction of an endocrine gland. The classic example of this mechanism in animals is the failure of oropharyngeal ectoderm to differentiate completely into trophic hormone-secreting cells of the adenohypophysis in dogs, resulting in pituitary dwarfism.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 12.1.4.2 SECONDARY HYPOFUNCTION OF AN ENDOCRINE GLAND

In this mechanism a destructive lesion in one organ, such as the pituitary gland, interferes with the secretion of a trophic hormone. This results in hypofunction of the target endocrine gland. Large, endocrinologically inactive pituitary neoplasms in adult dogs, cats, and other animals can interfere with the secretion of multiple pituitary trophic hormones and result in clinically detectable hypofunction of the adrenal cortex (Fig. 12-17), follicular cells of the thyroid gland, and gonads.

**Fig. 12-17 Secondary hypofunction of an endocrine gland, brain, pituitary gland and adrenal glands, dog.** A large nonfunctional chromophobe adenoma (A) has invaded and completely destroyed the adenohypophysis and hypothalamus, and infiltrated into the thalamus. Destruction of the adenohypophysis has resulted in a lack of secretion of thyrotropin, adrenocorticotropin, and other pituitary trophic hormones. This resulted in severe trophic atrophy of the adrenal cortex (*arrowheads*), especially the adrenocorticotrophic hormone–dependent zona fasciculata and zona reticularis, and consequently, in a relatively more prominent medulla (M). (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 12.1.4.3 PRIMARY HYPERFUNCTION OF AN ENDOCRINE GLAND

This is one of the most important pathologic mechanisms of endocrine disease in animals. The cells of a lesion, often a neoplasm derived from endocrine cells, autonomously synthesize and secrete a hormone at a rate in excess of the body's ability to use and degrade it, thereby resulting in a syndrome caused by hormone excess. Examples are summarized in [Table 12-1](#). These include hyperfunction of secretory cells of the adrenal medulla, follicular cells and C (parafollicular) cells of the thyroid gland, parathyroid chief cells, and  $\beta$  cells of the pancreatic islets.

Table 12-1 Primary Hyperfunction of an Endocrine Gland

Neoplasia	Hormone	Lesion/Sign
Acidophil adenoma (pituitary gland)	Growth hormone	Acromegaly
Adrenal cortical adenoma/carcinoma	Estrogen	Feminization
Pheochromocytoma (adrenal medulla)	Norepinephrine	Hypertension
Thyroid follicular cell adenoma	$T_4$ , $T_3$	$\uparrow$ Basal metabolic rate
C-cell adenoma/carcinoma (thyroid gland)	Calcitonin	Osteosclerosis
Parathyroid gland chief cell adenoma	Parathyroid hormone	Fibrous osteodystrophy
Pancreatic $\beta$ -cell adenoma/carcinoma	Insulin	Hypoglycemia

705

### 12.1.4.4 SECONDARY HYPERFUNCTION OF AN ENDOCRINE GLAND

706

In this mechanism of endocrine disease, a lesion in one organ (e.g., adenohypophysis) secretes an excess of a trophic hormone that leads to long-term stimulation and hypersecretion of a hormone by a target organ. The classic example in animals is the ACTH-secreting neoplasm derived from pituitary corticotrophs in dogs ([Fig. 12-18](#)). The functional disturbances and lesions are the result primarily of increased blood cortisol concentrations resulting from the ACTH-stimulated hypertrophy and hyperplasia of the cells of the zona fasciculata and zona reticularis of the adrenal cortex. In some aging dogs, with notable adrenal cortical enlargement and functional disturbances of cortisol excess, no gross or histopathologic evidence of a neoplasm is present in the pituitary gland. These animals can have a change in negative feedback control due to an age-related increase in monoamine oxidase- $\beta$  in the hypothalamus and increased metabolism of dopamine. This outcome results in reduced inhibition of ACTH production by the pars intermedia of the pituitary gland, leading to severe corticotroph hyperplasia, increased ACTH concentration in the blood, and long-term stimulation of the adrenal cortex, resulting in the syndrome of cortisol excess.

### 12.1.4.5 HYPERSECRETION OF HORMONES OR HORMONELIKE FACTORS BY NONENDOCRINE NEOPLASMS

Certain neoplasms of nonendocrine tissue in both animals and human beings either secrete new humoral substances or hormones that share chemical and/or biologic characteristics with the “native” hormones secreted by an endocrine gland. Most of the recently discovered humoral substances secreted by nonendocrine neoplasms are peptides rather than steroids, iodothyronines, or catecholamines. The nonpeptide hormones require more complex biosynthetic pathways and are infrequently produced by cancer cells. Pseudohyperparathyroidism or humoral hypercalcemia of malignancy is a clinical syndrome primarily produced by the autonomous hypersecretion of parathyroid hormone–related peptide (PTH-rP) by cancer cells. PTH-rP interacts with the parathyroid hormone receptor in target cells (e.g., bone and kidneys) and

## Pathologic Basis of Veterinary Disease, 4th Edition

results in persistent, often life-threatening hypercalcemia. A well-characterized example of this disease mechanism in animals is the adenocarcinoma of the apocrine glands of the anal sac in dogs. These neoplasms produce PTH-rP, which mimics the action of PTH and results in an accelerated mobilization of calcium from bone by osteoclasts leading to the development of persistent hypercalcemia. Serum PTH concentrations are lower in dogs with apocrine carcinomas than in controls, and PTH concentrations are undetectable in neoplastic tissue.

706

The chronic secretion of ACTH has resulted in hypertrophy and hyperplasia of secretory cells of the zona fasciculata and zona reticularis in the adrenal cortex (*arrows*) and excessive secretion of cortisol. (*Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.*)

12.1.4.6

### ENDOCRINE DYSFUNCTION DUE TO FAILURE OF TARGET CELL RESPONSE

This mechanism of endocrine disease is widely accepted now that there is a more complete understanding of how hormones interact with target cells to convey their biologic message. Failure of target cells to respond to a hormone can be due to a lack of adenyl cyclase in the cell membrane or to an alteration in hormone receptors on the cell surface. Hormone is secreted in normal or increased amounts by the cells of the

## Pathologic Basis of Veterinary Disease, 4th Edition

---

endocrine gland. For example, insulin resistance in obese animals and human beings can result from a decrease or down-regulation of receptors on the surface of target cells. Receptor down-regulation develops in response to a chronic increase in insulin stimulated by the hyperglycemia resulting from excessive food intake. Secretory cells in the corresponding endocrine gland (i.e., pancreatic islets) undergo compensatory hypertrophy and hyperplasia in an attempt to secrete additional hormone.

An interesting form of hypoparathyroidism has been reported in human patients in whom the inability of target cells to respond is the result of a defect in the cAMP-mediated signal transduction that results from inactivating mutations of a specific nucleotide regulatory protein in the cell membrane. Human patients with pseudohypoparathyroidism develop hypocalcemia and hyperphosphatemia in spite of hyperplastic parathyroid glands and increased blood concentration of PTH.

### 12.1.4.7 ENDOCRINE HYPERACTIVITY DUE TO DISEASES OF OTHER ORGANS

The best characterized example of this is the hyperparathyroidism that develops as a result of chronic renal failure or nutritional imbalance. In the renal form, hyperphosphatemia occurs because of a decreased glomerular filtration rate, resulting in a reciprocal decline in serum calcium and parathyroid stimulation. Subsequently the progressive destruction of cells of the proximal convoluted tubules interferes with the metabolic activation of vitamin D by  $1\alpha$ -hydroxylase in the kidneys, leading to decreased intestinal calcium absorption and continued parathyroid stimulation. This rate-limiting step in the metabolism of vitamin D is controlled by multiple factors, including levels of PTH, serum phosphorus, and several other hormones. The intestinal absorption of calcium is impaired and results in the development of progressive hypocalcemia; the hypocalcemia leads to long-term parathyroid gland stimulation and subsequently to the development of generalized demineralization of the skeleton. Nutritional hyperparathyroidism develops in animals fed abnormal diets that are either too low in calcium, too high in phosphorus, or deficient in cholecalciferol (e.g., in New World nonhuman primates).

Hyperfunction of an endocrine organ also can result from hormonal imbalances induced by xenobiotic chemicals. For example, in rodents undergoing chronic toxicity testing, hyperactivity of the pituitary gland can occur resulting in increased incidences of neoplasms in the gonads or mammary glands. Excess production of LH, usually because of disruption of negative feedback control by estrogen or testosterone, increases the incidence of tubulostromal adenomas and granulosa cell neoplasms in the ovaries of mice and of Leydig (interstitial) adenomas of the testes in rats.

### 12.1.4.8 ENDOCRINE DYSFUNCTION RESULTING FROM ABNORMAL HORMONE DEGRADATION

#### 12.1.4.8.1 Decreased Degradation

The rate of secretion of a hormone by an endocrine gland can be normal with this mechanism, but because of the decreased rate of degradation, blood concentrations are persistently increased, thereby simulating a syndrome of hypersecretion. The classic example of this mechanism is the syndrome of feminization because of hyperestrogenism and from decreased hepatic degradation of estrogens in patients with cirrhosis. Hypercalcemia, due in part to a decrease in the ability of proximal convoluted tubular epithelial cells in the diseased kidneys to degrade PTH (along with a decrease in urinary excretion of calcium), is occasionally reported in dogs with chronic renal disease.

## Pathologic Basis of Veterinary Disease, 4th Edition

12.1.4.8.2

### Increased Degradation

The long-term administration of various xenobiotics, such as phenobarbital to laboratory rodents, results in the induction of hepatic enzymes (e.g., thyroxine [ $T_4$ ] uridine diphosphate glucuronyl transferase) that increase the degradation rate of thyroxine. This chronic disruption of the thyroid-pituitary gland axis results in increased TSH secretion. In rodents, especially male rats, the development of thyroid follicular cell neoplasms often is increased in chronic toxicity and oncogenicity studies with certain new drugs and chemicals.

12.1.4.9

### IATROGENIC SYNDROMES OF HORMONE EXCESS

The administration of an exogenous hormone can influence the activity of target cells either directly or indirectly and result in important functional disturbances. It is well recognized that the chronic administration of potent preparations of adrenal cortical steroids at inappropriately large daily doses (for the symptomatic treatment of various diseases) can produce most of the functional disturbances that are secondary to an endogenous hypersecretion of cortisol. Increased concentrations of exogenous cortisol result in notable atrophy of the adrenal cortex, particularly the ACTH-dependent zona fasciculata and zona reticularis (Fig. 12-19). Similarly the administration of excessively large doses of insulin can result in hypoglycemia, and an excess of  $T_4$  or triiodothyronine ( $T_3$ ) can result in hyperthyroidism, especially in certain species, such as cats, which have limited capacities to conjugate  $T_4$  with glucuronic acid and thus enhance its biliary excretion.

707

708

**Fig. 12-19 Iatrogenic syndrome of hormone excess, adrenal glands, dog.**

Hyperadrenocorticism, caused by long-term administration of exogenous corticosteroids, has resulted in notable trophic atrophy of the adrenocorticotrophic hormone–dependent zona fasciculata and zona reticularis of the adrenal cortex (C). The adrenal medulla (M) occupies a relatively greater percentage of the atrophic adrenal gland than of a normal adrenal gland. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The administration of progestogens to dogs indirectly results in a syndrome of growth hormone excess. For example, the injection of medroxyprogesterone acetate for the prevention of estrus in dogs stimulates the expression of the growth hormone gene in the mammary glands and results in elevated circulating growth hormone concentrations, producing many of the clinical manifestations of acromegaly. The excessive skin folds (Fig. 12-20), expansion of interdigital spaces, and abdominal enlargement in dogs with iatrogenic acromegaly are related to the protein anabolic effects of growth hormone. Elongation of bones in response to exogenous progestogens requires functional growth plates and osteogenic surfaces.

### 12.2 DISEASES OF THE ENDOCRINE SYSTEM

#### 12.2.1 DISORDERS OF THE ADENOHYPOPHYSIS

##### 12.2.1.1 HYPOPITUITARISM

##### 12.2.1.1.1 Aplasia and Prolonged Gestation

Subnormal function of the fetal endocrine system, seen especially in ruminants, can disrupt normal fetal development and result in prolonged gestation. In Guernsey and Jersey cattle, a genetically determined failure of development (aplasia) of the adenohypophysis has been described, but the neurohypophysis develops normally. This aplasia results in a lack of fetal pituitary trophic hormone secretion during the last trimester and hypoplasia of target endocrine organs, namely the adrenal cortex, gonads, and follicular cells of the thyroid gland. Fetal development is normal up to approximately 7 months of gestation, but then fetal growth ceases irrespective of the length of time the viable fetus is retained in the uterus.

**Fig. 12-20 Iatrogenic acromegaly, beagle, center (compared with unaffected littermates, left and right).** Note the coarseness of the facial features and the marked thickening and folding of the skin of the face. These characteristic changes are the result of the protein anabolic effects of somatotropin (produced by hyperplastic ductular epithelial cells), which has been stimulated by the exogenous administration of medroxyprogesterone acetate. (Courtesy Dr. P. Concannon, College of Veterinary Medicine, Cornell University.)

Prolongation of gestation occurs in ewes that ingest the plant *Veratrum californicum* between days 12 and 14 of gestation. *Veratrum californicum* contains potent alkaloids that inhibit neural tube development, resulting in cyclopia and extensive malformations of the CNS and hypothalamus in lambs.

Arrhinencephalia and lack of development of nasal bones accompany the formation of a proboscis-like structure. Although the adenohypophysis may be present in some cases, it is unable to secrete normal amounts of trophic hormones (ACTH) because it lacks the necessary fine control derived from the hypothalamic-releasing hormones. Pregnancy is maintained until a cesarean section is performed or the lamb dies in utero. Although the lambs retained in the uterus continue to grow beyond the normal gestation period, target endocrine organs in the fetus are hypoplastic, and the adrenal cortex does not differentiate completely into the three distinctive zones that secrete corticosteroid hormones.

708

Two concepts have emerged from the study of prolonged gestation in cattle and sheep; (1) Fetal hormones are necessary for final growth and development of the fetus in certain animals, and (2) normal parturition at term in these species requires an intact fetal hypothalamic-pituitary-adrenocortical axis working in concert with trophoblasts of the placenta.

709

Although the presence or absence of functional adenohypophyseal tissue determines whether the fetus continues to grow in utero, the pathogenesis of prolongation of the gestational interval is similar in these two examples. The subnormal development of the fetal adrenal cortex in calves and lambs results in an inadequate secretion of cortisol and a failure to induce 17 $\alpha$ -hydroxylase in the placenta, which converts precursor molecules, such as progesterone, to estrogen. Thus the dam's circulating progesterone is maintained near midgestational concentrations, and the notable increase in estrogens that normally occurs at term resulting in parturition is absent. The estrogen surge, when it occurs, stimulates prostaglandin synthesis in the uterus, which results in smooth muscle contractions and biochemical changes in collagen along the birth canal that normally permit delivery of the fetus.

### 12.2.1.1.2

#### Pituitary Cysts and Pituitary Dwarfism

Pituitary dwarfism in dogs is usually due to a failure of the oropharyngeal ectoderm of Rathke's pouch to differentiate into trophic hormone-secreting cells of the pars distalis. This results in a progressively enlarging, multiloculated cyst and an absence of the adenohypophysis (Fig. 12-21). Other cysts originating in the craniopharyngeal duct or the pharyngeal hypophysis can also become large enough to induce clinical signs.

Juvenile panhypopituitarism occurs most frequently in German shepherd dogs, but it has been reported in spitz, toy pinscher, and Karelian bear dogs. The dwarf pups appear normal from birth to about 2 months of age. Subsequently the slower growth, retention of puppy hair coat, and lack of primary guard hairs gradually become evident (Fig. 12-22). A bilaterally symmetric alopecia develops gradually and often progresses to complete alopecia except for the head and tufts of hair on the legs. There is progressive hyperpigmentation of the skin until the skin is uniformly brownish-black over most of the body. Adult German shepherd dogs with panhypopituitarism vary in size from as small as 2 kg to nearly half normal size, depending on whether the failure of formation of the adenohypophysis is partial or complete.

The mode of inheritance is simple autosomal recessive. The activity of somatomedin, also known as insulin-like growth factor (a non-species-specific, cartilage growth-promoting peptide whose production in the liver and plasma activity is controlled by somatotropin) is low in dwarf dogs. Intermediate somatomedin activity is present in phenotypically normal ancestors suspected to be heterozygous carriers.

## Pathologic Basis of Veterinary Disease, 4th Edition

Assays for somatomedin provide a useful indirect measurement of circulating growth hormone activity in dogs with suspected pituitary dwarfism if canine growth hormone assays are not available.

**Fig. 12-21 Cystic Rathke's pouch, brain, sagittal section, dog.** A large, multiloculated cyst (C) is noted on the ventral aspect of this brain where the adenohypophysis would normally be located. (Courtesy College of Veterinary Medicine, University of Illinois.)

**Fig. 12-22 Panhypopituitarism ("pituitary dwarfism"), 5-month-old German shepherd and littermate.** The unaffected littermate weighed 27.3 kg, whereas the dwarf puppy weighed only 4 kg. The pituitary dwarf has retained its puppy hair coat. (From Alexander JE: *Can Vet J* 3:83, 1962.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 12.2.1.2 HYPERPITUITARISM AND NEOPLASMS OF THE ADENOHYPOPHYSIS

#### 12.2.1.2.1 Pars Intermedia Adenomas

Adenomas derived from cells of the pars intermedia are the most common type of pituitary gland neoplasm in horses and the second most common type in dogs, but they are rare in other species.

709

Adenomas develop in older horses, more frequently in females. Nonbrachycephalic breeds of dogs have adenomas of the pars intermedia more often than brachycephalic breeds.

710

Adenomas of the pars intermedia in dogs are either functionally inactive and result in varying degrees of hypopituitarism and diabetes insipidus, or endocrinologically active and secrete excessive levels of ACTH, leading to bilateral adrenal cortical hyperplasia and a syndrome of cortisol excess. Endocrinologically active (ACTH-secreting) adenomas of the pars intermedia in dogs have prominent groups of corticotrophs that have abundant eosinophilic cytoplasm and more widely scattered follicles.

Two cell populations have been identified in the pars intermedia of normal dogs by immunohistochemistry. The predominant cell type (A cell) stains strongly for  $\alpha$ -MSH, as in the pars intermedia of other species. A second cell type (B cell) in the canine pars intermedia stains intensely for ACTH but not for  $\alpha$ -MSH. This second cell population accounts for the high bioactive ACTH concentration found in the pars intermedia of dogs and most likely gives rise to corticotroph adenomas of the pars intermedia in dogs with the syndrome of cortisol excess.

The clinical syndrome reported with neoplasms of the pars intermedia in horses is characterized by polyuria, polydipsia, polyphagia, muscle weakness, somnolence, intermittent hyperpyrexia, and generalized hyperhidrosis. The affected horses often develop hirsutism because of a failure to seasonally shed hair. The hair over most of the trunk and extremities is long (up to 10 to 12 cm), abnormally thick, wavy, and often matted (Fig. 12-23). Horses with larger neoplasms sometimes have insulin-resistant hyperglycemia and glycosuria, probably due to the down-regulation of insulin receptors on target cells induced by chronic excessive intake of feed and hyperinsulinemia. The disturbances in carbohydrate metabolism, ravenous appetite, hypertrichosis, and hyperhidrosis are considered to be primarily a reflection of deranged hypothalamic function caused by compression of the overlying hypothalamus by the large pituitary neoplasms. The hypothalamus is the primary center for homeostatic regulation of body temperature, appetite, and cyclic shedding of hair.

**Fig. 12-23 Hirsutism, skin, horse.** The hirsutism is the result of a failure to shed hair due to an adenoma of the pars intermedia. (*Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.*)

In addition to their space-occupying effects, some adenomas of the pars intermedia are endocrinologically active. Plasma cortisol and immunoreactive adrenocorticotropin (iACTH, molecular weight 4500 Da) concentrations can be modestly elevated in horses with pars intermedia adenomas. The cortisol concentrations often lack normal diurnal rhythm and are not suppressed by either large or small doses of dexamethasone. The modest increases of plasma iACTH appear to be caused by the different processing of proopiomelanocortin (POMC) in neoplasms derived from cells of the pars intermedia. This could explain the normal or slightly increased blood cortisol concentrations and normal or mildly hyperplastic adrenal cortices observed in some horses with adenomas of the pars intermedia. The concentrations of ACTH in the neoplasm have been reported to be six times that of the normal pars intermedia and only approach the concentrations found in the pars distalis of normal horses. The plasma and neoplasm concentrations of pars intermedia-derived peptides (CLIP [corticotrophin-like intermediate lobe peptide],  $\alpha$ -MSH,  $\beta$ -MSH, and  $\beta$ -endorphin [ $\beta$ -END]) are disproportionately increased (40 times or more) compared with those of ACTH, apparently as the result of selective posttranslational processing of POMC in a manner similar to that of the normal pars intermedia.

Adenomas of the pars intermedia have immunohistochemical staining similar to that of the nonneoplastic equine pars intermedia. The findings include a strong, diffuse cytoplasmic reaction for POMC, a moderately strong reaction for  $\alpha$ -MSH and  $\beta$ -END, a weak reaction for ACTH, and negative immunostaining for prolactin, glial fibrillary acidic protein, and neuron-specific enolase. Two antisera directed against different parts of the *N*-terminal fragment of human (h) POMC differ in their immunoreactivity. Immunostaining of neoplastic cells was stronger with anti-h<sup>1-48</sup> *N*-POMC antisera than with anti-h<sup>1-76</sup> *N*-POMC antisera. These immunohistochemical findings support the biochemical studies that suggest horses with pituitary adenomas derived from the cells of the pars intermedia develop a unique

## Pathologic Basis of Veterinary Disease, 4th Edition

clinical syndrome that is the result of hypothalamic and neurohypophyseal derangement and of an autonomous production of excess amounts of POMC-derived peptides. Although many of the functional disturbances in horses with pituitary adenomas (e.g., diabetes insipidus, polyphagia, hyperpyrexia, hyperhidrosis, and hirsutism) appear to be the result of hypothalamic or neurohypophyseal dysfunction, other behavioral signs (e.g., docility and diminished responsiveness to painful stimuli) could be related to increased plasma and cerebrospinal fluid concentrations of  $\beta$ -END. The clinical syndrome in horses with pituitary neoplasms is distinctly different from that of Cushing's disease in dogs, cats, and human patients.

710

711

**Fig. 12-24 Adenoma, brain, pituitary gland, horse.** The pituitary gland is notably enlarged because of an adenoma (A) of the pars intermedia. (Courtesy College of Veterinary Medicine, University of Illinois.)

In dogs, adenomas of the pars intermedia result in only a moderate enlargement of the pituitary gland. The pars distalis is readily identifiable and sharply demarcated from the anterior margin of the neoplasm, usually by an incomplete layer of condensed stroma. The neoplasm can extend across the residual hypophyseal lumen and result in compression atrophy, but it usually does not invade the pars distalis. The posterior lobe is incorporated within the neoplasm, but the infundibular stalk is intact. Histologically, canine pars intermedia adenomas are composed of numerous large colloid-filled follicles lined by partially ciliated simple columnar epithelium scattered among nests of variably sized chromophobic cells.

In horses, adenomas of the pars intermedia often are large neoplasms that extend out of the fossa hypophysialis and severely compress the overlying hypothalamus (Fig. 12-24). The adenomas are yellow

## Pathologic Basis of Veterinary Disease, 4th Edition

to white, are multinodular, and enclose the pars nervosa. When the neoplasm is incised, the pars distalis usually can be identified as a compressed subcapsular rim of tissue on the anterior margin. A sharp line of demarcation remains between the neoplasm and the compressed pars distalis. The neoplastic cells are arranged in cords and nests along the capillaries and connective tissue septa and are large, cylindrical, spindle-shaped, or polyhedral with oval hyperchromatic nuclei (Fig. 12-25). The pattern is often reminiscent of that of the prominent pars intermedia of normal horses. Ribbons of more cuboidal to columnar neoplastic cells occasionally form follicular structures that have dense eosinophilic colloid.

**Fig. 12-25 Adenoma, pituitary gland, pars intermedia, horse.** Adenoma composed of cords and ribbons of well-differentiated, tall cuboidal to columnar cells with ample amounts of granular basophilic cytoplasm. H&E stain. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

12.2.1.2.2

### ACTH-Secreting (Corticotroph) Adenomas

Functional (endocrinologically active) neoplasms arising in the pituitary gland most likely are derived from corticotroph (ACTH-secreting) cells in the pars distalis but can also arise from the pars intermedia of dogs. These neoplasms cause a clinical syndrome of cortisol excess (Cushing's disease) resulting in gluconeogenic, lipolytic, protein catabolic, and antiinflammatory activities. These neoplasms are encountered most frequently in dogs, particularly in adult to aged boxers, Boston terriers, and dachshunds.

The pituitary gland is consistently enlarged (Fig. 12-18); however, neither the occurrence nor the severity of functional disturbances appear to be directly related to the size of the neoplasm. Because the diaphragma sellae are incomplete in the dog, the line of least resistance is dorsal and expansion of the gradually enlarging pituitary mass is in this direction. This results in invagination into the infundibular cavity, dilation of the infundibular recess and the third ventricle with eventual compression or replacement of the hypothalamus, and possible extension of the neoplasm into the thalamus (Fig. 12-17).

711

712

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Bilateral enlargement of the adrenal glands occurs in dogs with functional corticotroph adenomas ([Fig. 12-18](#)). This enlargement is due to cortical hyperplasia, primarily of the zonae fasciculata and reticularis. Nodules of yellow-orange cortical tissue are often found outside the capsule and extending down into and compressing the adrenal medulla.

Pituitary corticotroph adenomas are composed of well-differentiated, large or small, chromophobic cells supported by fine connective tissue septa. The cytoplasm of the neoplastic cells usually is devoid of secretory granules, but stains immunohistochemically for ACTH and MSH. Hormone-containing secretory granules can be demonstrated by electron microscopy in functional corticotroph adenomas of dogs.

### 12.2.1.3 HYPOPITUITARISM AND NEOPLASMS OF THE ADENOHYPOPHYSIS

#### 12.2.1.3.1 Endocrinologically Inactive Chromophobe Adenomas

Nonfunctional pituitary neoplasms occur in dogs, cats, laboratory rodents, and parakeets but are uncommon in other species. Although chromophobe adenomas seem endocrinologically inactive, they can cause significant functional disturbances and clinical signs by virtue of their compressing and causing atrophy of adjacent portions of the pituitary gland and also dorsal extension into the overlying brain ([Fig. 12-26](#)). The clinical disturbances result either from the lack of secretion of pituitary trophic hormones and diminished target organ function (e.g., adrenal cortex; [Fig. 12-17](#)) or from dysfunction of the CNS. Affected animals often have decreased spontaneous activity, incoordination and disturbances of balance, are weak, and sometimes collapse after exercise. Chronically affected animals are blind and have dilated and fixed pupils because of compression and disruption of the optic nerves by dorsal extension of the pituitary neoplasms ([Fig. 12-26](#)). Endocrinologically inactive pituitary adenomas often become large before they cause clinical signs or kill the animal ([Figs. 12-17 and 12-26](#)).

Clinical signs reported with nonfunctional pituitary adenomas and hypopituitarism are not specific and could be confused with other disorders of the CNS, such as brain neoplasms and encephalitis, or with chronic renal disease. There is no effect on body stature secondary to compression of the pars distalis and interference with growth hormone secretion because these neoplasms usually arise in adult animals that have already completed their growth. However, atrophy of the skin and loss of muscle mass could be related in part to a lack of the protein anabolic effects of growth hormone. Interference with the secretion of pituitary trophic hormones often leads to a reduced basal metabolic rate because of decreased TSH secretion and hypoglycemia secondary to trophic atrophy of the adrenal cortex ([Fig. 12-17](#)).

Fig. 12-26 **Adenoma, pituitary gland, dog.** A large pituitary adenoma (A) has extended dorsally and compresses the overlying brain. The optic chiasm (*arrow*) is also severely compressed. The adenohypophysis, neurohypophysis, and hypothalamus have been destroyed by the neoplasm. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

### 12.2.1.3.2

#### Pituitary Gland Carcinomas

Pituitary gland carcinomas are uncommon neoplasms compared with adenomas but have been seen in older dogs and cattle. They usually are endocrinologically inactive but can cause significant functional disturbances by destroying the pars distalis and neurohypophyseal system, leading to panhypopituitarism and diabetes insipidus. Carcinomas are large and invade extensively into the overlying brain, along the ventral aspect of the cranial cavity, and into the basisphenoid bone where they cause osteolysis. Metastases occur infrequently to cervical lymph nodes or distant sites, such as the spleen or liver. Carcinomas are highly cellular and often have large areas of hemorrhage and necrosis. Giant cells, nuclear pleomorphism, and mitotic figures are encountered more frequently than in adenomas.

### 12.2.1.3.3

#### Craniopharyngiomas (Intracranial Germ Cell Tumors)

Craniopharyngiomas are benign neoplasms derived from epithelial remnants of the oropharyngeal ectoderm of the craniopharyngeal duct (Rathke's pouch). They often occur in animals younger than those with other types of pituitary neoplasms and are present in either suprasellar or infrasellar locations. Craniopharyngioma is one cause of panhypopituitarism and dwarfism in young dogs because it causes subnormal secretion of somatotrophin and other trophic hormones at an early age, before closure of the growth plates.

The reclassification of some pleomorphic neoplasms in the suprasellar region of younger dogs from craniopharyngiomas to germ cell tumors has recently been proposed. The diagnosis of germ cell tumors

712

713

## Pathologic Basis of Veterinary Disease, 4th Edition

was based on three criteria: (1) midline suprasellar location, (2) presence within the tumor of several distinct cell types (one population resembles a seminoma or dysgerminoma and others suggest teratomatous differentiation into secretory glandular and squamous elements), and (3) positive staining for  $\alpha$ -fetoprotein.

Craniopharyngiomas and suprasellar germ cell tumors often are large and grow along the ventral aspect of the brain, where they can surround several cranial nerves. In addition, they extend dorsally into the hypothalamus and thalamus (Fig. 12-27). The resulting clinical signs often occur because of a combination of the following:

- A lack of secretion of pituitary trophic hormones resulting in trophic atrophy and subnormal function of the adrenal cortex and thyroid gland, atrophy of the gonads, and failure to attain somatic maturation because of a lack of secretion of growth hormone
- Disturbances in water metabolism (polyuria, polydipsia, low urine specific gravity, and osmolality) resulting from an interference in the synthesis and release of ADH by the large neoplasm
- Deficits in cranial nerve function
- CNS dysfunction due to extension into the overlying brain

**Fig. 12-27 Craniopharyngioma (C), pituitary area, adrenal glands, thyroid glands, dog.** The neoplasm has extended dorsally through the hypothalamus and compressed the thalamus (*black arrows*). The neoplasm has also destroyed the adenohypophysis and neurohypophysis, resulting in severe trophic atrophy of the adrenal cortex (*white arrow*). The adrenal glands consist predominantly of medulla (*M*) surrounded by a thin rim of cortex (capsule plus zona glomerulosa). Although the thyroid follicular cells are atrophic, the overall gland (*T*) size is within normal limits because of colloid involution of the follicles. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Microscopically, craniopharyngiomas have alternating solid and cystic areas. The solid areas are composed of nests of cuboidal, columnar, or squamous epithelial cells with focal areas of mineralization. The cystic spaces are lined by either columnar or squamous cells and contain keratin debris and colloid.

### 12.2.2 DISORDERS OF THE NEUROHYPOPHYSIS

#### 12.2.2.1 DIABETES INSIPIDUS

Diabetes insipidus results when inadequate ADH is produced (hypophyseal form) or when target cells in the kidneys lack the biochemical pathways necessary to respond to the secretion of normal or increased circulating concentrations of ADH (nephrogenic form). The hypophyseal form of diabetes insipidus results from compression and destruction of the pars nervosa, infundibular stalk, or supraoptic nucleus in the hypothalamus. The disruption of ADH synthesis or secretion in hypophyseal diabetes insipidus can be due to a large pituitary neoplasm, a dorsally expanding cyst, inflammatory granuloma, or traumatic injury to the skull with hemorrhage and glial proliferation in the neurohypophyseal tissue. Compression or disruption of the posterior lobe, infundibular stalk, and hypothalamus by neoplastic cells interrupts the transport of ADH in nonmyelinated axons from the site of production, primarily in the supraoptic nucleus of the hypothalamus, to the site of release in the capillary plexus of the pars nervosa.

Animals with diabetes insipidus excrete large volumes of hypotonic urine, which in turn necessitates the ingestion of large amounts of water to prevent dehydration and hyperosmolality of body fluids. Urine osmolality is decreased below normal plasma osmolality (approximately 300 mmol/L), in both hypophyseal and nephrogenic forms of diabetes insipidus. In response to water deprivation, urine osmolality still remains below that of the plasma in both forms of diabetes insipidus in contrast to increased osmolality observed in normal animals. Urine osmolality is increased above that of plasma in response to exogenous ADH in the hypophyseal form, but this increase does not occur in nephrogenic diabetes insipidus, a useful feature in differential diagnosis.

713

### 12.2.3 DISORDERS OF THE ADRENAL CORTEX

714

#### 12.2.3.1 HYPOADRENOCORTICISM (ADDISON'S DISEASE)

Adrenal cortical insufficiency was the first recognized endocrine disease and is a common endocrinopathy in dogs. Clinical signs are a result of deficient production of any or all classes of corticosteroids (mineralocorticoids, glucocorticoids, and adrenal sex steroids). The synthesis and secretion of mineralocorticoids are reduced, resulting in marked alterations of serum potassium, sodium, and chloride concentrations (Fig. 12-5). Less potassium is excreted by the kidneys (hypokaliuria), resulting in severe hyperkalemia. Less sodium and chloride are reabsorbed from renal tubules, leading to varying degrees of hypernatruria and hyperchloriduria and a corresponding decline in blood concentrations of these ions. The severe hyperkalemia frequently produces notable cardiovascular disturbances. The pronounced bradycardia that develops in some dogs (heart rate of 50 or fewer beats per minute) does not change with exercise, but does predispose to weakness and circulatory collapse after minimal exertion.

A decreased production of glucocorticoids results in several characteristic functional disturbances of hypoadrenocorticism. A failure of gluconeogenesis and increased sensitivity to insulin contributes to the development of moderate hypoglycemia. Hyperpigmentation of the skin occurs in some dogs with

## Pathologic Basis of Veterinary Disease, 4th Edition

long-standing adrenocortical insufficiency and is a common finding in human Addisonian patients. This lesion results from a lack of negative feedback to the pituitary gland and the increased release of ACTH (and possibly MSH). The plasma cortisol concentrations in dogs with hypoadrenocorticism are low and range from 0.1 to 1.5 µg/dl. Because of the severe atrophy of the adrenal cortex, little or no increase in blood cortisol concentration results after the administration of ACTH.

12.2.3.1.1

### Adrenalitis

Bacterial and parasitic agents frequently localize in the adrenal glands and produce varying degrees of inflammation and necrosis. Focal inflammatory processes usually are suppurative, arising in the course of bacterial septicemias. The adrenal capsule provides an effective barrier against direct invasion by inflammatory reactions in adjacent tissue. Granulomatous adrenalitis due to *Histoplasma capsulatum*, *Coccidioides immitis*, or *Cryptococcus neoformans* occasionally occurs in dogs and cats. Multiple granulomas with central areas of necrosis and calcification can destroy nearly the entire adrenal cortex. *Toxoplasma gondii* produces necrosis with an infiltration of histiocytes in the adrenal cortex of many species of animals. Experimental evidence suggests that large local concentrations of antiinflammatory steroids in the adrenal cortex (e.g., cortisol and corticosterone) suppress local cell-mediated immunity and permit the progressive growth of certain fungi (e.g., *Histoplasma capsulatum*, *Coccidioides immitis*), protozoa (e.g., *Babesia darlingi*, *Babesia jellisoni*, or *Toxoplasma gondii*), and bacteria (e.g., *Mycobacterium tuberculosis*).

12.2.3.1.2

### Adrenocortical Hemorrhage (Waterhouse-Friderichsen Syndrome)

Massive, diffuse, often bilateral adrenal cortical hemorrhage, a condition known as Waterhouse-Friderichsen syndrome, is an uncommon but fatal consequence of overwhelming sepsis (Fig. 12-28). Although frequently seen in conjunction with endotoxic shock, Waterhouse-Friderichsen syndrome can also result from gram-positive organisms and noninfectious causes, such as anticoagulant therapy and trauma.

12.2.3.1.3

### Idiopathic Adrenocortical Atrophy

Bilateral idiopathic adrenal cortical atrophy is an entity in young adult dogs that results in hypoadrenocorticism. The adrenal cortex is reduced to one tenth or less of its normal thickness because of a marked reduction of all layers of the cortex. It consists primarily of the adrenal capsule (Fig. 12-29). Thus the adrenal medulla becomes relatively more prominent and, along with the capsule, makes up the bulk of the remaining adrenal gland. The precise pathogenesis of idiopathic adrenal cortical atrophy is unknown, but the lesion is most likely immune mediated. Early in the disease, multiple foci of lymphocytes and plasma cells are interspersed between the adrenal sinusoids and adrenal cortical cells. The capsule is thickened by condensation from the collapse of the adrenal cortex and fibroblastic proliferation. Pituitary gland lesions have not been observed in dogs with idiopathic adrenal cortical atrophy involving all three zones of the adrenal cortex, including the zona glomerulosa, which is not under ACTH control. By comparison, atrophy of the adrenal cortex due to a destructive pituitary gland lesion that decreases ACTH secretion is characterized by severe atrophy only of the two inner cortical zones (zona fasciculata and zona reticularis). The zona glomerulosa remains intact (Fig. 12-17), and thus these animals do not have electrolyte abnormalities because the secretion of aldosterone remains within normal limits.

714

715

**Fig. 12-28 Adrenocortical hemorrhage (Waterhouse-Friderichsen syndrome), adrenal gland, horse.** **A**, Diffuse hemorrhage (*arrow*) affecting the adrenal cortex is frequently seen in endotoxic shock. **B**, Subgross of diffuse hemorrhage (*arrow*) affecting the adrenal cortex. **Fig. 12-29 Adrenal cortical atrophy, brain stem and pituitary gland, adrenal glands, dog.** Bilateral atrophy of all three cortical layers (*arrows*) is characteristic of hypoadrenocorticism. The pituitary gland (*arrowhead*) was grossly normal with microscopic evidence of corticotroph hyperplasia. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

### 12.2.3.2 HYPERADRENOCORTICISM (CUSHING'S SYNDROME OR DISEASE)

The clinical manifestations and lesions characteristic of the syndrome of hyperadrenocorticism result primarily from chronic overproduction of cortisol by hyperactive cells of the adrenal cortex. Affected dogs develop a spectrum of functional disturbances and lesions resulting from the combined glyconeogenic, lipolytic, protein catabolic, and antiinflammatory effects of the glucocorticoid hormones on many organs. The disease is insidious and slowly progressive. Cortisol excess or Cushing's syndrome is one of the most common endocrinopathies in adult and aged dogs but occurs infrequently in cats and rarely in other domestic animals.

The increase in circulating cortisol concentrations in dogs with hyperadrenocorticism can result from one of several different pathogenic mechanisms. The most common cause of Cushing's syndrome is Cushing's disease in which a functional corticotroph (ACTH-secreting) adenoma of the pituitary gland causes bilateral adrenal cortical hypertrophy and hyperplasia (Fig. 12-18). The cortex of each adrenal gland is widened considerably as a result of diffuse and nodular hyperplasia, primarily in the zona fasciculata. Functional adrenal gland neoplasms are an infrequent (10% to 15% of cases) cause of Cushing's syndrome in the dog. Many of the clinical signs and lesions of naturally occurring hyperadrenocorticism can be induced by the long-term, daily administration of large doses of corticosteroids. To accurately separate the different pathogenic mechanisms responsible for cortisol excess, plasma cortisol concentrations must be evaluated with the animal in the basal state and then after dexamethasone (large or small dose) suppression and ACTH stimulation.

Appetite and food intake often are increased as a direct result of either the hypercortisolism or damage caused by compression of the hypothalamic appetite centers by a large, dorsally expanding pituitary gland neoplasm. The muscles of the extremities and abdomen are weakened and atrophied, resulting in gradual

715

abdominal enlargement (Fig. 12-30), lordosis, muscle trembling, and a straight-legged, skeletal-braced posture assumed to support the body's weight. Hepatomegaly caused by increased deposits of lipid and glycogen (steroid hepatopathy; see Fig. 8-44) can contribute to the development of the distended, often pendulous, abdomen. The muscular asthenia and wasting are the result of increased catabolism of structural proteins combined with diminished protein synthesis in skeletal myocytes from the influence of long-term cortisol excess. Cutaneous lesions occur frequently in dogs with hyperadrenocorticism. The initial changes in the skin often are observed over points of wear (e.g., neck, flanks, behind the ears) and over bony prominences. These initial cutaneous changes spread in a bilaterally symmetric pattern to involve a significant percentage of the body surface (Fig. 12-30). Cutaneous lesions caused by excessive cortisol include atrophy of the epidermis and pilosebaceous units, combined with loss of collagen and elastin in the dermis and subcutis. Cutaneous calcification or calcinosis cutis is a characteristic lesion and occurs in up to 30% of dogs with hypercortisolism. Numerous calcium crystals are deposited along collagen and elastin fibers in the dermis and can penetrate through the atrophic and thinned epidermis. These calcium deposits occur in dogs with normal blood calcium and phosphorus concentrations. This manifestation of hypercortisolism is most likely related to the glyconeogenic and protein catabolic action of cortisol, which results in the rearrangement of the molecular structure of such proteins as collagen and elastin, and the formation of an organic matrix that attracts and binds calcium. Severe calcification also occurs in other tissues, such as lungs, active skeletal muscle, and the stomach.

**Fig. 12-30 Cushing's-like disease, hypercortisolism, dog, poodle.**

Hypercortisolism followed exogenous corticosteroid administration for the treatment of idiopathic adrenal cortical hyperplasia. Muscle asthenia is the cause of the pendulous abdomen. Note the alopecia of the skin of the abdomen, ventral cervical region, and tail.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 12.2.3.2.1 Congenital Adrenal Hyperplasia (Adrenogenital Syndrome)

Congenital adrenal hyperplasia is an entity of hypoadrenocorticism and hyperadrenocorticism. Affected individuals are deficient in an enzyme such as 21-hydroxylase, involved in both mineralocorticoid and glucocorticoid synthesis. As a consequence of reduced cortisol levels, there is a compensatory increase in ACTH secretion resulting in adrenal cortical hyperplasia. Subsequent steroid synthesis is diverted to the androgenic pathway, which is independent of 21-hydroxylase. Excessive androgen production leads to virilization and sexual ambiguity in newborns and premature closure of epiphyses. Hereditary adrenal hyperplasia occurs in rabbits of the IIIVO/ahj strain. The mode of inheritance, as in human beings, is autosomal recessive. Notable, bilateral adrenal enlargement is evident as early as day 19 of gestation. Although affected rabbit kits are viable, they die soon after birth. Pomeranians are predisposed to a congenital adrenal hyperplasia-like syndrome and associated dermatosis; however, no mutations in the 21-hydroxylase enzyme have been found in the small group of Pomeranians evaluated.

### 12.2.3.2.2 Hyperplasia and Neoplasia of Adrenal Cortex

#### 12.2.3.2.2.1 Accessory adrenal tissue

Accessory or ectopic adrenal cortical tissue is common in the adrenal glands of adult to aged animals and can be found in the capsule, cortex, and medulla. Many of these nodules arise either as evaginations of the cortex into the capsule and surrounding periadrenal adipose tissue or invaginations of the cortex into the medulla.

#### 12.2.3.2.2.2 Hyperplasia

Nodular hyperplasia is common in the adrenal glands as well-defined spherical nodules in the cortex or attached to the capsule (Fig. 12-31). Hyperplastic nodules are usually multiple, bilateral and yellow, and involve any of the three zones of the cortex. Histologically the nodules near the capsule resemble the zona glomerulosa and sometimes the zona fasciculata. The lipid content in these hyperplastic nodules is retained in circumstances that reduce the amount of lipid in the normal adrenal cortex. Hyperplastic cortical nodules are most common in older horses, dogs, and cats. Nodular hyperplasia of the zona reticularis has been seen in animals with functional disturbances suggestive of androgen excess (e.g., greater muscle mass, well-developed crest, clitoral hypertrophy, and mammary gland involution).

Diffuse cortical hyperplasia results in a uniform, usually bilateral, enlargement of the adrenal cortices. Notable hypertrophy and hyperplasia of cells of the zona fasciculata and zona reticularis occur in response to an autonomous hypersecretion of ACTH by a corticotroph adenoma of the pituitary gland (Fig. 12-18). The cytoplasm of the hyperplastic cells of the zona fasciculata is vacuolated because of the lipid content. Cells of the outer zona glomerulosa can be compressed by the expansion of the inner two zones. Nodular hyperplasia can be present in a diffusely hyperplastic cortex.

716

717

**Fig. 12-31 Nodular adrenal cortical hyperplasia, adrenal gland, dog.** Multiple discrete nodules (*arrows*) of cortical hyperplasia extend into the medulla. (*Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.*)

12.2.3.2.2.3

### Cortical adenomas

Adenomas of the adrenal cortex occur most frequently in older dogs and only sporadically in horses, cattle, and sheep. Castrated male goats have a greater incidence of cortical adenomas than intact males. Although these neoplasms are usually incidental findings at necropsy, they are occasionally endocrinologically active. Cortical adenomas are well demarcated and usually are a single, unilateral nodule. Larger cortical adenomas are yellow to red, distort the contour of the gland, compress the adjacent cortical parenchyma, and are partially or completely encapsulated (Fig. 12-32). Cortical adenomas often develop in an adrenal gland with multiple nodules of hyperplasia and can be difficult to differentiate grossly from hyperplastic nodules. However, these hyperplastic nodules consist of multiple small foci, usually in both adrenal glands, without encapsulation, and often with extracapsular nodules of hyperplastic cortical tissue. Cortical adenomas are composed of well-differentiated cells that resemble secretory cells of the normal zona fasciculata or zona reticularis. The cytoplasm of neoplastic cells is abundant and lightly eosinophilic and filled with lipid droplets. Adenomas are partially or completely surrounded by a fibrous connective tissue capsule of varying thickness and a rim of compressed cortical parenchyma.

12.2.3.2.2.4

### Cortical carcinomas

Adrenal cortical carcinomas occur less frequently than adenomas and have been reported most often in cattle and older dogs, but they also occur infrequently in other species. Carcinomas develop in adult to older dogs. There is no apparent breed or sex prevalence. Adrenal carcinomas are larger than adenomas and are more likely to be bilateral. In dogs, they are composed of a variegated, yellow-red, friable tissue (Fig. 12-33) and can invade extensively into surrounding tissue, such as the wall of the caudal vena cava, resulting in thrombus formation. Carcinomas attain considerable size in cattle (up to 10 cm or more in diameter) and have multiple areas of calcification or ossification.

Fig. 12-32 **Adrenocortical adenoma, adrenal gland, horse.** Note the well-demarcated, large, yellowish-tan, adrenocortical adenoma (A) compressing the adjacent unaffected medulla (M). C, Adrenal cortex. (Courtesy Dr. B. Weeks, College of Veterinary Medicine, Texas A&M University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Fig. 12-33 **Adrenocortical carcinoma and contralateral cortical atrophy, adrenal glands, dog.** The adrenal gland (right) has a large adrenocortical carcinoma that is almost half the size of an adult kidney (left). Multifocal to coalescing areas of hemorrhage and necrosis are apparent (arrowheads) in this tumor. The cortex of the contralateral adrenal gland (lower) is notably thinned (arrow) because of severe trophic atrophy of the zona fasciculata and zona reticularis. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

Carcinomas are composed of more highly pleomorphic secretory cells than adenomas and are subdivided by a fine fibrovascular stroma. The affected adrenal gland usually is completely obliterated by the carcinoma (Fig. 12-33). The growth pattern of neoplastic cells varies between neoplasms and within the same carcinoma, and can be trabecular, lobular, or focal. Neoplastic cells usually are large and polyhedral, and they have prominent nucleoli and densely eosinophilic or vacuolated cytoplasm.

Carcinomas and adenomas of the adrenal cortex in dogs occasionally are functional and secrete excessive amounts of cortisol. The clinical syndrome produced by excessive secretion by adrenal cortical carcinomas can be complicated by signs produced by compression of adjacent organs when the neoplasm is large; by invasion into the aorta or caudal vena cava, which can lead to intraabdominal hemorrhage; and by metastases to distant sites (e.g., liver, kidneys, mesenteric lymph nodes, and lungs). Functional cortical adenomas and carcinomas are responsible for severe atrophy of the contralateral adrenal cortex because of negative feedback inhibition of pituitary ACTH secretion by the increased blood cortisol concentrations (Fig. 12-33). The atrophic cortex consists primarily of the adrenal capsule and zona glomerulosa. Atrophy is also present in the remnants of the adrenal cortex compressed by functional adenomas. Because of the lack of cortical tissue, the adrenal medulla appears more prominent (Fig. 12-33).

717

718

### 12.2.3.2.2.5

#### Functional proliferative lesions in ferrets

Adrenal gland neoplasms are the second most common neoplasm reported in ferrets, and they are being recognized with increasing frequency as more are being kept as pets and living longer. The adrenal gland enlargements are either bilateral (approximately 45%) as a result of diffuse (most frequent) or nodular hyperplasia, or unilateral (approximately 55%) as a result of adrenal cortical carcinoma or cortical adenoma. Adrenal gland neoplasms develop in adult ferrets (mean age 5 years) with females more frequently affected than males (sex ratio  $\geq 2:1$ ), and in animals gonadectomized at an early age (2 to 4 months). The latter finding is attributed to chronic trophic stimulation of the zona reticularis by LH.

A unique histologic feature of adrenocortical carcinomas in ferrets is the presence of a spindle cell component to the neoplastic cortical cells. These spindle cells express smooth muscle actin and arise from capsular or subcapsular smooth muscle cells, or they might represent a morphologically distinct adrenocortical cell. An emerging histologic variant of ferret adrenocortical carcinomas demonstrating increased invasiveness is characterized by myxoid differentiation (Fig. 12-34). In addition, immunoreactivity to the transcription factor GATA-4 has been identified as a marker of anaplasia in ferret adrenocortical tumors.

Clinical signs in ferrets with adrenal cortical neoplasms include vulvar enlargement, bilaterally symmetric alopecia (especially on the ventral abdomen and medial aspects of the rear legs), polyuria, polydipsia, and the presence of a palpable mass at the cranial pole of the kidneys (left side greater frequency than right). Other functional disturbances—including anemia and thrombocytopenia, pyometra, and endometrial hyperplasia in females, and squamous metaplasia of prostatic ductular epithelium and cystic prostatic disease in males—are changes consistent with an overproduction of estrogenic steroids by the adrenal gland neoplasms. Some of the functional disturbances resemble those seen in intact females with persistent or prolonged estrus; ferrets are seasonally polyestrous and are induced ovulators. About one third of ferrets with adrenal cortical neoplasms also have neoplasms derived from the insulin-producing  $\beta$  cells of the pancreatic islets. These neoplasms can produce increased concentrations of serum insulin resulting in hypoglycemia that can lead to seizures, episodic lethargy, ptyalism, ataxia, and hind leg weakness.

Fig. 12-34 **Adrenocortical carcinoma with myxoid differentiation, adrenal gland, ferret.** Note that the cystic spaces lined by neoplastic cells contain abundant mucinous material. Alcian blue stain. (From Peterson RA, Kiupel M, Capen CC: Vet Pathol 40:136-142, 2003.)

The most consistent endocrinologic change in ferrets with adrenal gland neoplasms is increased plasma concentrations of estradiol-17 $\beta$ . It is presumed that the estradiol-17 $\beta$  is produced directly by the neoplastic cells, but alternatively the adrenal gland neoplasms could secrete androgenic steroids that are aromatized in the skin and possibly elsewhere aromatized to estrogenic steroids. No increase in circulating estradiol-17 $\beta$  concentrations is found in response to exogenous ACTH, but plasma concentrations decrease after adrenalectomy. Plasma cortisol and corticosterone concentrations in ferrets with adrenal gland neoplasms are in the low to normal range and are not increased greatly in response to exogenous ACTH. Plasma cortisol is not decreased after unilateral adrenalectomy, and the contralateral adrenal cortex is not atrophic as would be expected if the adrenal gland neoplasm was secreting excess cortisol. The clinical signs in ferrets with adrenal cortical neoplasms can be effectively reversed by adrenalectomy (especially of the left side if there is no macroscopic enlargement) but not by chemotherapy with mitotane (*o,p'*-DDD). Complete regrowth of hair usually occurs by 2 to 3 months after adrenalectomy.

### 12.2.4 DISORDERS OF THE ADRENAL MEDULLA

#### 12.2.4.1 PROLIFERATIVE LESIONS

##### 12.2.4.1.1 Adrenal Medullary Hyperplasia

Diffuse or nodular adrenal medullary hyperplasia appears to precede the development of pheochromocytoma in bulls and human beings with C-cell neoplasms of the thyroid gland. The

718

719

## Pathologic Basis of Veterinary Disease, 4th Edition

proliferated chromaffin cells are nonencapsulated but compress the surrounding adrenal cortex (Fig. 12-35). Hyperplastic cells are round to oval and have pale basophilic cytoplasm. Some bulls with prominent diffuse medullary hyperplasia often have a few small nodules of proliferated medullary cells. Medullary hyperplasia is diagnosed on the basis of the following criteria: an increased adrenal weight; a decrease in cortical to medullary ratio because of an increase in the size and number of medullary cells; and numerous mitotic figures in the adrenal medulla.

**Fig. 12-35 Hyperplasia, adrenal medulla, bull.** Bilateral diffuse hyperplasia of adrenal medulla in a bull with a concomitant C-cell carcinoma of the thyroid gland. The expanded adrenal medulla (*bottom*) has compressed the surrounding adrenal cortex (*arrows*). H&E stain. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

### 12.2.4.1.2 Neoplasms

#### 12.2.4.1.2.1 Neuroblastomas and ganglioneuromas

Neuroblastomas usually occur in young animals, arise from primitive neuroectodermal cells, and form large intraabdominal masses. The tumors are composed of small neoplastic cells that have hyperchromatic nuclei and scant amounts of cytoplasm and resemble lymphocytes. Neoplastic cells tend to aggregate around blood vessels, forming pseudorosettes. Neurofibrils or unmyelinated nerve fibers can be demonstrated in neuroblastomas.

Ganglioneuromas are benign neoplasms composed of multipolar ganglion cells and neurofibrils, and have a prominent fibrous connective tissue stroma. The surrounding adrenal cortex is often severely compressed. Occasionally, neoplastic cells in adrenal medullary neoplasms differentiate into two cell lines, resulting in pheochromocytoma and ganglioneuroma in the same adrenal gland.

### Pheochromocytomas

Pheochromocytomas are the most common neoplasms in the adrenal medullas of animals, occurring most often in cattle and dogs and infrequently in other species. Calcitonin-secreting C-cell neoplasms of the thyroid gland occasionally develop concurrently with pheochromocytomas in bulls and human beings. Extraadrenal pheochromocytomas, referred to as paragangliomas, also occur infrequently in the abdomen.

Pheochromocytomas often are large (10 cm or more in diameter) and replace most of the affected adrenal gland. Smaller neoplasms are completely surrounded by a thin, compressed rim of adrenal cortex (Fig. 12-36). Large pheochromocytomas are multilobular and variegated light brown to yellow-red as a result of areas of hemorrhage and necrosis. Malignant pheochromocytomas invade through the capsule of an adrenal gland into adjacent structures, such as the caudal vena cava (Fig. 12-37), and metastasize to distant sites including the liver, regional lumbar aortic, and renal lymph nodes or lungs. Histologically, neoplastic cells vary from small, round to polyhedral cells to large, pleomorphic cells with multiple hyperchromatic nuclei. The cytoplasm is lightly eosinophilic, finely granular, and often indistinct.

Functional pheochromocytomas composed of epinephrine- and/or norepinephrine-secreting cells have been reported infrequently in animals. Tachycardia, edema, and cardiac hypertrophy observed in several dogs and horses with pheochromocytomas were attributed to excessive catecholamine secretion.

719

Arteriolar sclerosis and widespread medial hyperplasia of arterioles have been reported in dogs with pheochromocytomas and clinical signs suggestive of paroxysmal hypertension. Hypertension was detected in 43% of dogs with pheochromocytomas; all hypertensive dogs had concurrent diseases that could have contributed to the increase in blood pressure. Infrequently, hyperadrenocorticism occurs concurrently in dogs with pheochromocytoma and could contribute to the development of hypertension, particularly during digital manipulation of the affected adrenal gland during surgery.

720

**Fig. 12-36 Pheochromocytoma, adrenal gland, horse. A** pheochromocytoma compressing the adjacent unaffected adrenal cortex. (Courtesy College of Veterinary Medicine, University of Illinois.)

Fig. 12-37 **Pheochromocytoma, kidney, adrenal gland, caudal vena cava, dog.** A large pheochromocytoma (*P*) has obliterated the adrenal gland medial to the kidney (*K*) and has extensively invaded into the lumen of the caudal vena cava (*arrow*).  
(Courtesy Dr. April Paulman, College of Veterinary Medicine, University of Illinois.)

Norepinephrine is the predominant catecholamine extracted from pheochromocytomas in dogs. This is similar to the finding in normal pups, in which norepinephrine is the predominant catecholamine; in adult dogs, epinephrine predominates in adrenal medullary tissues. The catecholamine content of pheochromocytomas in bulls with concurrent C-cell neoplasms of the thyroid gland is greater than in the normal adrenal medulla. Urinary excretion of free unconjugated catecholamines and metabolites of catecholamines, such as vanillylmandelic acid, are increased in bulls with pheochromocytomas.

### 12.2.5 DISORDERS OF THE THYROID GLAND

#### 12.2.5.1 DEVELOPMENTAL DISTURBANCES

##### 12.2.5.1.1 Accessory Thyroid Tissue

The thyroid gland originates embryologically as a thickened plate of epithelium in the ventral aspect of the pharynx. The complex embryogenesis of the thyroid frequently leads to the formation of accessory thyroid tissue. This accessory thyroid tissue is most typically located in the mediastinum but can be located anywhere from the base of the tongue to the diaphragm. About 50% of adult dogs have nodules of accessory thyroid tissue embedded in the adipose around the base of the heart and the origin of the aorta.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The follicular structure and function are the same as those of the main thyroid lobes. Attempts to induce hypothyroidism in the dog by surgical thyroidectomy are usually unsuccessful because the accessory thyroid tissue readily responds to the prompt increase in endogenous TSH secretion, and can undergo sufficient hyperplasia to sustain adequate hormone production. This accessory thyroid tissue can also undergo neoplastic transformation.

12.2.5.1.2

### Thyroglossal Duct Cysts

Thyroglossal duct cysts develop most frequently in dogs and pigs and are present occasionally in other animals. They form as a result of persistence of portions of the midline embryologic primordia of the thyroid gland, which migrates caudally from the ventral aspect of the primitive pharynx to form the thyroid lobes postnatally. These cysts are present in the ventral aspect of the cervical region in dogs and are fluctuant masses that can rupture and form a tract to the exterior. Their lining epithelium consists of multiple layers of follicular cells in which colloid-containing follicles are found occasionally. These cells sometimes undergo neoplastic transformation and give rise to papillary carcinomas.

12.2.5.2

### HYPOTHYROIDISM

Hypothyroidism is a well-recognized and clinically important disease in dogs but is encountered only occasionally in other animals. Although the disease occurs in many adult purebred and mixed breed dogs, certain breeds such as the golden retriever, Doberman pinscher, dachshund, Shetland sheep dog, Irish setter, miniature schnauzer, cocker spaniel, and Airedale are more commonly affected. Hypothyroidism in dogs is usually the result of primary lesions in the thyroid gland, particularly idiopathic follicular collapse and lymphocytic thyroiditis. Less common causes of hypothyroidism include bilateral nonfunctional follicular cell neoplasms and severe iodine-deficient goiter. Hypothyroidism due to long-standing pituitary gland or hypothalamic lesions, which prevent the release of either TSH or thyrotropin-releasing hormone, is encountered infrequently in the dog. In these cases, the thyroid gland is moderately reduced in size and composed of colloid-distended follicles, lined by flattened follicular cells.

Many functional disturbances reported with hypothyroidism occur because of a reduction in basal metabolic rate. A gain in body weight without an associated change in appetite occurs in some hypothyroid dogs.

Thinning of the hair coat is often accompanied by bilaterally symmetric alopecia. Areas affected initially by hair loss are those receiving frictional wear, such as the tail and cervical area.

720

721

Fig. 12-38 **Hypothyroidism, skin, dog.** Hyperkeratosis (*arrows*) has resulted in thickening of the epidermis of the skin. H&E stain. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

Hyperkeratosis is a consistent finding in hypothyroidism and results clinically in an increased scaliness of the skin. When severe, it occurs as circular scaly patches resembling seborrhea. Microscopically, hyperkeratosis (Fig. 12-38) involves the external root sheath, resulting in follicular keratosis. Hyperpigmentation, especially in such localized areas of alopecia as the dorsal aspect of the nose and distal portion of the tail, occurs in many dogs with hypothyroidism. Myxedema may also develop because of the accumulation of glycosaminoglycans and hyaluronic acid in the dermis and subcutis. These substances bind considerable amounts of water, which results in notable thickening of the skin. Microscopically, mucins appear as granular or fibrillar material in hematoxylin and eosin (H&E) stained sections.

Reproductive abnormalities include lack of libido, reduced sperm count, abnormal or absent estrus cycles, and reduced conception rates. In chronic hypothyroidism, spermatogenic epithelium in the testes is often notably atrophic.

Hypothyroidism in dogs is accompanied by decreased circulating thyroidal hormone concentrations and decreased  $^{131}\text{I}$  uptake by the thyroid gland. In dogs with hypothyroidism, the concentration of  $\text{T}_4$  is usually below  $0.8 \mu\text{g/dl}$  (normal  $1.5$  to  $3.4 \mu\text{g/dl}$ ) and that of  $\text{T}_3$  is below  $50 \text{ ng/dl}$  (normal  $48$  to  $150 \text{ ng/dl}$ ). In the euthyroid dog,  $\text{T}_4$  concentrations will at least double 8 hours after intravenous or intramuscular injection of TSH. In dogs with hypothyroidism, the  $\text{T}_4$  concentrations do not change significantly after injection of TSH.

**Fig. 12-39 Atherosclerosis, hypothyroidism with marked hyperlipidemia, heart, coronary arteries, dog.** Note the atherosclerosis (*arrows*) of the coronary arteries which are thickened, firm, yellow-white, and often beaded. (*Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.*)

Serum cholesterol concentrations are often greatly increased (300 to 900 mg/dl) in many hypothyroid dogs (normal 40 to 80 mg/dl). The marked hypercholesterolemia in long-standing and severe hypothyroidism results in a variety of secondary lesions, including atherosclerosis, hepatomegaly, and glomerular and corneal lipidosis. Atherosclerosis of coronary (Fig. 12-39) and cerebral vessels develops in dogs that have severe hypothyroidism and long-standing hyperlipidemia.

### 12.2.5.2.1 Idiopathic Follicular Atrophy (“Collapse”)

In follicular atrophy, the loss of follicular epithelium and disruption of follicles is progressive and the gland is replaced by adipose connective tissue with only a minimal inflammatory response. The gland usually is smaller and lighter in color than normal. The early lesion in dogs with mild clinical signs of hypothyroidism appears to be confined to one part of the thyroid gland. The affected part is composed of small follicles that contain little colloid and are lined by tall columnar follicular cells. A more advanced form of follicular atrophy is present in dogs with clinical hypothyroidism and low blood concentrations of thyroidal hormones. These thyroid glands are notably reduced in size and are composed predominantly of adipose connective tissue with only a few clusters of small follicles containing vacuolated colloid.

721

Lymphocytic thyroiditis in dogs, obese strains of chickens, nonhuman primates, and Buffalo rats closely resembles Hashimoto's disease of human beings. Although the exact pathogenetic mechanism in the dog is not completely established, evidence suggests a polygenic pattern of inheritance similar to that observed in human beings. The immunologic basis of the development of chronic lymphocytic thyroiditis in human beings and dogs appears to be through production of autoantibodies. These are usually directed against thyroglobulin or a microsomal antigen such as thyroperoxidase and infrequently against the TSH receptor, a nuclear antigen, or a second colloid antigen from thyroid follicular cells. Thyroglobulin autoantibodies have been found in 48% of pet dogs with hypothyroidism. Laboratory beagles with naturally occurring lymphocytic thyroiditis also have circulating thyroidal autoantibodies, but the focal thyroiditis usually is not severe enough to induce clinical signs of hypothyroidism.

Microscopic lesions consist of multifocal to diffuse infiltrates of lymphocytes, which occasionally form nodules, plasma cells, and macrophages. Thyroid follicles are small and lined by columnar epithelial cells; lymphocytes, macrophages, and degenerate follicular cells are often present in the colloid, which is vacuolated (Fig. 12-40). Thyroid C cells are present as small nests or nodules between follicles and often are more prominent than those in normal dogs. Some remaining follicular cells appear to be transformed into large oxyphilic cells with densely eosinophilic granular cytoplasm.

**Fig. 12-40 Lymphocytic thyroiditis in a dog with severe hypothyroidism.** A lymphocyte (*L*) and macrophage (*M*) are present in the colloid (*C*) of a thyroid follicle. A plasma cell (*P*) within the follicular basement membrane (*B*) is infiltrating between thyroid follicular cells. TEM. Uranyl acetate and lead citrate stain. (From Gosselin SJ, Capen CC, Martin SL: Vet Immunol Immunopathol 3:185-201, 1982.)

### 12.2.5.3 HYPERTHYROIDISM

Hyperthyroidism or thyrotoxicosis resulting from elevated circulating levels of  $T_4$  and  $T_3$  commonly occurs in middle-aged to older cats and rarely in dogs. The condition in cats is associated with a spectrum of functional proliferative lesions, whereas in dogs it is due to thyroid neoplasms.

Clinical signs result from an increased rate of basal metabolism. Consequently, animals are polyuric and polydipsic, and frequently lose weight despite a voracious appetite. Weakness and fatigue, nervousness or hyperexcitability, and hyperthermia and heat intolerance are also present. In addition, cardiac manifestations of hyperthyroidism, such as tachycardia and dysrhythmias, are well documented in animals; however, secondary hypertrophic cardiomyopathy characterized by concentric hypertrophy is primarily restricted to cats and rats.

In general, the likelihood of animals developing clinical hyperthyroidism secondary to thyroid neoplasms depends on (1) the capability of neoplastic cells to synthesize  $T_4$  and  $T_3$  (e.g., well-differentiated thyroid neoplasms that form follicles and produce colloid are more likely to synthesize thyroid hormones than poorly differentiated solid neoplasms), and (2) the extent of the increase in circulating concentrations of  $T_4$  and  $T_3$ , which depends on a balance between the rate of secretion of thyroid hormones by the neoplasm, and the rate of degradation of thyroid hormones. Dogs have a much more efficient enterohepatic excretory mechanism for thyroid hormones, which is difficult to overload, than cats; therefore, clinical hyperthyroidism in dogs with functional thyroid follicular cell neoplasms is infrequent. Cats are very sensitive to phenol and phenol derivatives and have a poor ability to conjugate phenolic compounds such as  $T_4$  with glucuronic acid and excrete the  $T_4$  glucuronide into the bile. The capacity of conjugation of  $T_3$  with sulfate is limited and easily overloaded in cats.

#### 12.2.5.3.1 Functional Proliferative Lesions in Cats

A spectrum of proliferative lesions that secrete excess thyroidal hormones (e.g., adenomas and multinodular hyperplasia) is common in the thyroid glands of adult and aged cats. Since the late 1970s, there has been a dramatic increase in the incidence of neoplasms and other focal proliferative lesions in the thyroid glands of cats and these have resulted in hyperthyroidism. Hyperthyroidism is one of the two most common endocrine diseases in adult to aged cats (diabetes mellitus being the other). Before 1980, clinical hyperthyroidism was infrequently diagnosed in cats. The reason for the apparently increased incidence is uncertain, but appears to be related in part to (1) a larger population of geriatric cats receiving veterinary medical care, (2) improved assays for thyroid hormones, (3) detailed characterization of the clinical syndrome, and (4) increased awareness by veterinary clinicians of its common occurrence in adult to aged cats. In addition, there does appear to be a real increase in the incidence of feline hyperthyroidism over the past 30 years. Potential risk factors that have been reported include a predominantly indoor environment, regular treatment with flea powders, exposures to herbicides and fertilizers, a diet primarily of canned food, and non-Siamese breeds (10 times greater occurrence). It has been suggested that wide variations (excessive to inadequate) in dietary iodine intake over prolonged periods could play a role in the pathogenesis of hyperthyroidism in cats.

The disease in cats is mechanistically different from that of Graves' disease in human patients in that hyperthyroid cats do not have increased concentrations of circulating thyroid-stimulating immunoglobulins, which are comparable to long-acting thyroid stimulator (LATS) in human beings

## Pathologic Basis of Veterinary Disease, 4th Edition

(LATS is an autoantibody that binds to the TSH receptor and activates follicular cells). Purified immunoglobulin G, prepared from hyperthyroid cats, significantly increases  $^3\text{H}$ -thymidine incorporation into DNA and stimulates thyroid follicular cell proliferation fifteenfold but does not stimulate intracellular cAMP production. The  $^3\text{H}$ -thymidine incorporation can be completely inhibited by a specific TSH receptor blocking antibody. These data suggest that increased titers of thyroid growth-stimulating immunoglobulins are present in cats with hyperthyroidism and most likely act by the TSH receptor. In cats, the disease most closely resembles toxic nodular goiter in human patients with mutations in genes encoding for either the TSH receptor or the  $G_{sa}$  protein. Mutations in  $G_{sa}$  that correspond to the mutations in human beings have been reported in a small group of hyperthyroid cats.  $G_{sa}$  is a G protein that mediates cAMP-dependent TSH signaling. Follicular cell proliferation, differentiation, and secretion of thyroid hormone result from constitutive activation of TSH signaling. In a separate study, all cases of feline follicular hyperplasia and adenomas evaluated by immunohistochemistry demonstrated overexpression of the c-ras oncogene. As was the case for activating  $G_{sa}$  mutations, overexpression of c-ras results in constitutive mitogenesis of thyroid follicular epithelial cells. Hyperplastic and neoplastic thyroid tissue from cats is transplantable into athymic (nude) mice and continues to overproduce  $T_4$  and  $T_3$  in a subcutaneous location.

Follicular cell adenomas, which often develop in a thyroid gland with multinodular hyperplasia, are more common than thyroid carcinomas. Follicles in the rim of thyroid tissue around a functional adenoma are notably enlarged and distended with colloid (colloid involution). The follicular cells are low cuboidal and atrophic with little evidence of endocytic activity in response to the increased concentrations of circulating thyroid hormones. In cats with solitary adenomas, the opposite thyroid lobe should be examined carefully for evidence of nodular hyperplasia or microadenomas. These small foci of multinodular follicular cell hyperplasia can be the cause of hyperthyroidism recurring several months to a year or more after surgical removal of a functional adenoma.

**Fig. 12-41 Hyperplasia, hyperthyroidism, thyroid glands, cat.**  
Multinodular follicular cell hyperplasia (*arrowheads*) involves both thyroid lobes. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

Hyperthyroidism in cats also occurs in association with bilateral multinodular adenomatous hyperplasia (goiter), which usually causes only slight enlargement of the affected lobe(s) (Fig. 12-41). In contrast to adenomas, areas of nodular hyperplasia are not encapsulated and the adjacent thyroid tissue is not compressed. Microscopically, hyperplastic nodules are composed of irregularly shaped, colloid-filled follicles lined by cuboidal follicular cells and these nodules are considered a preneoplastic lesion as they can coalesce and form a thyroid follicular cell adenoma.

Cats with hyperthyroidism usually have notably increased serum  $T_4$  and  $T_3$  concentrations. The serum  $T_4$  concentrations in cats with hyperthyroidism range from 3.4 to 30  $\mu\text{g/dl}$  (normal 1.5 to 5  $\mu\text{g/dl}$ ), and serum  $T_3$  concentrations range from 179 to 470  $\text{ng/dl}$  (normal 60 to 200  $\text{ng/dl}$ ). Moderately increased serum enzyme activities, including serum alanine aminotransferase (ALT, SGPT), serum aspartate aminotransferase (AST, SGOT), and especially alkaline phosphatase, occur in hyperthyroid cats.

Hyperthyroid cats often have disturbances of calcium homeostasis and a concomitant diffuse chief cell hyperplasia in the parathyroid glands. Blood ionized calcium and plasma creatinine concentrations are significantly decreased, whereas plasma phosphorus and intact parathyroid hormone (PTH) concentrations are increased. Hyperparathyroidism occurs in 77% of hyperthyroid cats, with PTH concentrations elevated up to 19 times that of the upper limit of the reference range. Hyperphosphatemia is present in approximately 40% of hyperthyroid cats. The mechanisms for the development of hyperphosphatemia in feline hyperthyroidism are uncertain but could be related in part to polyphagia, resulting in increased intestinal phosphorus absorption, increased catabolism of muscle proteins, release of phosphorus because of the gluconeogenic effects of the increased thyroid hormone concentrations, and increased bone resorption with release of phosphorus into the blood. Hyperparathyroidism and chief cell hyperplasia appear to be related to the reciprocal decline in amounts of circulating ionized calcium in response to the hyperphosphatemia. Increased blood phosphorus concentrations also could decrease renal $1\alpha$ -hydroxylase activity and decrease the production of the active form of vitamin D, thereby reducing intestinal calcium absorption. However, circulating concentrations of $1,25\text{-(OH)}_2\text{-dihydroxycholecalciferol}$ were not decreased in a limited number of hyperthyroid cats evaluated.	723 724
--	------------

### 12.2.5.3.2 Hyperplasia of Thyroid Follicular Cells (“Goiter”)

Goiter is a clinical term used to describe a nonneoplastic and noninflammatory enlargement of the thyroid gland. It develops in all domestic mammals, birds, and other submammalian vertebrates as a result of hyperplasia of follicular cells. Certain forms of thyroid hyperplasia, especially nodular, are difficult to differentiate from adenomas. The major pathogenetic mechanisms for the development of thyroid hyperplasia include iodine-deficient diets, goitrogenic compounds that interfere with thyroxinogenesis, excess dietary iodide, and genetically determined defects in the enzymes or thyroglobulin that are essential for the biosynthesis of thyroidal hormones. All these result in inadequate thyroxine synthesis and decreased blood concentrations of  $T_4$  and  $T_3$ , which are detected by the hypothalamus. This, in turn, stimulates the pituitary gland to increase the secretion of TSH, resulting in hypertrophy and hyperplasia of follicular cells.

### 12.2.5.3.3 Diffuse Hyperplastic and Colloid Goiter

Dietary iodine deficiency that resulted in diffuse hyperplastic goiter was common in many areas of the world before the widespread addition of iodized salt to animal diets. Iodine-deficient goiter still occurs worldwide in domestic animals, but cases are sporadic and few animals are affected. Marginally

## Pathologic Basis of Veterinary Disease, 4th Edition

---

iodine-deficient diets that contain goitrogenic compounds can cause severe thyroid follicular cell hyperplasia and goiter. Goitrogenic substances include thiouracil, sulfonamides, anions of the Hofmeister series, and a number of plants of the family Brassicaceae. Offspring of females fed iodine-deficient diets are likely to develop severe thyroidal follicular cell hyperplasia and have clinical signs of hypothyroidism. Both lateral lobes of the thyroid gland are uniformly enlarged in young animals as a result of diffuse hypertrophy and hyperplasia of follicular cells (Fig. 12-9). The enlargements, when extensive, result in palpable or visible swellings in the cranial ventral cervical area. The affected lobes are firm and dark red because an extensive interfollicular capillary network develops under the influence of long-term TSH stimulation.

Colloid goiter represents the involutionary phase of diffuse hyperplastic goiter in both young and adult animals. It develops either after sufficient amounts of iodide have been added to the diet or after the requirements for thyroid hormones have diminished as the animal ages. The notably hyperplastic follicular cells continue to produce colloid, but endocytosis of colloid from the lumen is decreased. This is a consequence of the diminished TSH concentrations produced in response to the return of blood  $T_4$  and  $T_3$  concentrations to normal. Both thyroid lobes are diffusely enlarged but are more translucent and lighter in color than in hyperplastic goiter. These differences in macroscopic appearances are the result of less vascularity in colloid goiter and development of macrofollicles distended with colloid. Follicles are progressively distended (Fig. 12-10) with densely eosinophilic colloid because of diminished TSH-induced endocytosis. As a result, follicular cells lining the macrofollicles are flattened and atrophic. The interface between the colloid and luminal surface of the follicular cells is smooth and the cells lack the endocytic vacuoles characteristic of actively secreting thyroid follicular cells. Some involuted follicles in colloid goiter have remnants of the papillary projections on follicular cells extending into their lumens.

The changes in diffuse hyperplastic and colloid goiters are uniform throughout the diffusely enlarged thyroid lobes. Follicles are irregular in size and shape in hyperplastic goiter because they contain varying amounts of colloid, which is lightly eosinophilic and vacuolated. Some follicles collapse because of the lack of colloid. Their lining epithelial cells are columnar and have deeply eosinophilic cytoplasm and small hyperchromatic nuclei, which are often situated in the basilar portions of the cells. The follicles are lined by single or multiple layers of hyperplastic follicular cells that, in some follicles, form papillary projections into the lumens (Fig. 12-42). Similar proliferative changes are present in ectopic thyroid tissue in the neck and mediastinum.

724

**Fig. 12-42 Hyperplastic goiter, thyroid gland, dog.** Papillary projection (*arrow*) extends into the follicular lumen. Note the partial collapse of the majority of the follicles. Periodic acid–Schiff reaction. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

Although seemingly paradoxical, an excess of iodide in the diet also can result in thyroid hyperplasia in animals and human beings. Foals of mares fed dry seaweed containing excessive iodide develop thyroid hyperplasia and clinically evident goiter. The thyroid glands of suckling animals are exposed to greater blood iodide concentrations than those of the dam because iodide is concentrated first by the placenta and then by the mammary gland. Increased blood iodide interferes with one or more steps of thyroidal hormone synthesis and secretion, leading to lowered blood  $T_4$  and  $T_3$  concentrations and resulting in a compensatory increase in pituitary TSH secretion. Excess iodine blocks the release of  $T_3$  and  $T_4$  by interfering with proteolysis of colloid by lysosomal enzymes in thyroid follicular cells.

#### 12.2.5.3.4

#### Multifocal Nodular Hyperplasia

Multifocal nodular hyperplasia in thyroid glands occurs in old horses, cats, and dogs and appears as multiple, white to tan nodules of variable size (Fig. 12-41), giving affected lobes a moderately enlarged and irregular contour. Multifocal nodular goiter in most animals except cats is endocrinologically inactive and is an incidental lesion at necropsy. However, functional thyroid adenomas often develop in the thyroid glands of aged cats with hyperthyroidism and multinodular hyperplasia of follicular cells. In contrast to thyroid adenomas, the areas of nodular hyperplasia are not encapsulated and cause minimal to no compression of adjacent parenchyma. Thus nodular goiter consists of multiple foci of hyperplastic follicular cells that are sharply demarcated but not encapsulated from the adjacent thyroid tissue.

The microscopic appearance of nodular hyperplasia often varies. Some hyperplastic follicular cells form small follicles with little or no colloid. Other nodules are composed of larger, irregularly shaped follicles

## Pathologic Basis of Veterinary Disease, 4th Edition

---

lined by one or more layers of columnar cells that form papillary projections into the lumen. Some of the follicles have undergone colloid involution and are filled with densely eosinophilic colloid. These changes appear to be the result of alternating periods of hyperplasia and colloid involution in the thyroid glands of aged animals.

### 12.2.5.3.5 Congenital Dyshormonogenetic Goiter

Congenital dyshormonogenetic goiter in sheep (Corriedale, Dorset Horn, Merino, and Romney breeds), Afrikaner cattle, and Saanen dwarf goats is inherited as an autosomal recessive trait. The subnormal growth rate, absence of normal wool development or the presence of a rough, sparse hair coat, subcutaneous myxedematous swellings, weakness, and sluggish behavior suggest that the affected young are clinically hypothyroid. Most lambs with congenital goiter either die shortly after birth or are markedly sensitive to the effects of adverse environmental conditions, particularly cold.

Thyroid lobes are symmetrically enlarged at birth because of an intense diffuse hyperplasia of follicular cells (Fig. 12-43). Thyroid follicles are often collapsed because of lack of colloid resulting from the notable endocytic activity. Follicles are lined by tall columnar follicular cells, which have dilated profiles of rough endoplasmic reticulum, large mitochondria, and dense lysosomal granules associated with the Golgi apparatus, but have few thyroglobulin-containing apical vesicles near the luminal plasma membrane. Numerous long microvilli extend into the follicular lumen.

Although thyroidal uptake and turnover of  $^{131}\text{I}$  are greatly increased compared with euthyroid controls, circulating  $\text{T}_4$  and  $\text{T}_3$  concentrations are consistently low. The lack of a defect in the iodide uptake or organification, plus an absence of normal 19S thyroglobulin in goitrous thyroids and only minute amounts of thyroglobulin-related antigens (0.01% of normal) suggest impaired thyroglobulin biosynthesis. A closely related or similar defect occurs in congenital goiter of sheep, cattle, and goats.

### 12.2.5.4 EPITHELIAL NEOPLASMS OF THE THYROID GLAND

#### 12.2.5.4.1 Follicular Cell Adenomas

Adenomas usually are white to tan, small, solid nodules that are well demarcated from the adjacent thyroid parenchyma. The affected thyroid lobe is only moderately enlarged and distorted; usually only a single adenoma is present in a thyroid lobe. A distinct, white, fibrous connective tissue capsule of variable thickness separates the adenoma from the adjacent compressed parenchyma. Some thyroid adenomas are composed of thin-walled cysts filled with a yellow-red fluid. Their external surfaces are smooth and covered by an extensive network of blood vessels. Small masses of neoplastic tissue remain in the wall and form rugose projections into the cyst. Adenomas are classified as follicular and papillary types; the follicular type is more common in the thyroid gland of animals.

725

726

midline ventral to the larynx (*L*) and trachea. (*Courtesy Dr. C.*  
*Capen, College of Veterinary Medicine, The Ohio State University.*)

### 12.2.5.4.2 Follicular Cell Carcinomas

In dogs, thyroid carcinomas occur more often than adenomas, but in cats adenomas are more common. Boxers develop thyroid carcinomas more frequently than any other breed of dog, but beagles and golden retrievers have a higher risk of developing thyroid carcinomas. Approximately 60% of thyroid carcinomas in dogs are clinically detectable by palpation as a firm mass in the neck, and by evidence of respiratory distress caused by tracheal compression. Carcinomas become fixed in position as a result of extensive local invasion of adjacent structures, whereas localized adenomas are freely movable under the skin. Neoplasms of thyroid origin also occur in accessory thyroidal tissue, located anywhere between the base of the tongue and the cranial mediastinum.

**Fig. 12-44 Thyroid carcinoma, thyroid gland, dog.** The poorly circumscribed and well-vascularized thyroid carcinoma (CA) is locally invasive and has extended into the wall of the esophagus. *E*, Esophageal mucosa. (Courtesy College of Veterinary Medicine, University of Illinois.)

Thyroid carcinomas often grow rapidly and invade adjacent structures, such as the trachea, esophagus, and larynx (Fig. 12-44). The earliest and most frequent site of metastasis is to lungs because thyroid carcinomas, early in the course of development, invade branches of the thyroid vein. The retropharyngeal and caudal cervical lymph nodes are infrequent sites of metastases.

#### 12.2.5.4.3

#### Thyroid C (Ultimobranchial) Cell Neoplasms

Neoplasms derived from C cells of the thyroid gland occur most frequently in adult to aged bulls, certain strains of laboratory rats, occasionally in horses and dogs, and infrequently in other species. The incidence of C-cell neoplasms increases with advancing age in bulls that also typically have increased vertebral bone density. A high percentage of aged bulls fed calcium-rich diets develop C-cell neoplasms (30%) or hyperplasia of C cells and ultimobranchial derivatives (15% to 20%). The cause of C-cell neoplasms is

726

unknown, but the chronic stimulation of C cells by large concentrations of calcium absorbed from the digestive tract can be responsible for their high incidence. A significant decline in the incidence of C-cell neoplasms occurs when the excessive calcium intake of bulls is reduced. Cows fed similar rations rarely develop proliferative lesions of C cells because of the greater physiologic requirements of pregnancy and lactation for calcium.

The syndrome of C-cell neoplasms in bulls is similar to the syndrome in human beings in that the tumors are commonly found in association with other endocrine neoplasms, especially bilateral pheochromocytomas and occasionally pituitary adenomas. There are two distinct forms of the familial cancer syndrome known as multiple endocrine neoplasia (MEN) in human beings. MEN1, also referred to as Werner syndrome, is due to a disease-causing mutation in the MEN1 gene and is characterized by primary hyperparathyroidism, pancreatic islet cell tumors that are predominantly gastrinomas, and pituitary tumors that are predominantly prolactinomas. Other lesions that can be associated with MEN1 include duodenal gastrinomas, carcinoids, thyroid adenomas, adrenocortical tumors, and lipomas. Mutations in the receptor tyrosine kinase RET result in MEN2. There are two subtypes, MEN2A (a.k.a. Sipple's syndrome) and MEN2B, both of which are associated with C-cell tumors, primary hyperparathyroidism, and pheochromocytomas. In addition, MEN2B patients frequently have mucosal neuromas and a marfanoid stature. There are increasing reports of multiple endocrine neoplasms in veterinary medicine in dogs, horses, a ferret, bulls, and Guernsey cattle. However, mutations in MEN1 or RET have never been documented in these cases. Furthermore, the tumors in animals are usually found in random endocrine organs, precluding definitive categorization as MEN1 or MEN2.

Both C-cell adenomas and carcinomas can contain deposits of amyloid. The source of the localized amyloid deposits in the neoplasms is uncertain, but the amyloid appears to be produced by the neoplastic cells, as amyloid deposits are not present in other organs. Amyloid deposition is consistently documented with medullary thyroid carcinoma in human beings, and amyloid has also been reported in certain other endocrine neoplasms. Amyloid in C-cell neoplasms is present between neoplastic cells, around vessels, and in the interstitium. Amyloid has been observed in bulls, horses, dogs, and laboratory rats, but in amounts varying (minimal to substantial) from case to case. Localized amyloid in C-cell tumors is derived from calcitonin.

### 12.2.5.4.3.1

#### Adenomas

C-cell adenomas occur as discrete, single, or multiple gray to tan nodules in one or both thyroid lobes. Adenomas are smaller (approximately 1 to 3 cm in diameter) than carcinomas and are separated from the adjacent thyroid gland parenchyma, which is compressed by a thin, fibrous connective tissue capsule. Larger C-cell adenomas replace most of the thyroid lobe, but a rim of dark, brown-red thyroid gland often is present on one side (Fig. 12-45). Histologically, thyroid C-cell adenomas are discrete, expansive masses composed of cells larger than a colloid-distended follicle. The adenoma is well circumscribed or partially encapsulated, and adjacent follicles are compressed to varying degrees. The neoplastic C cells are well differentiated and have abundant to clear, pale eosinophilic cytoplasm.

Fig. 12-45 **C-cell adenoma, thyroid gland, horse.** The adenoma (A) is confined by the thyroid capsule and a rim of compressed thyroid gland (*arrow*) at the periphery of the mass. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

12.2.5.4.3.2

### Carcinomas

Thyroid C-cell carcinomas result in extensive multinodular enlargements of one or both thyroid lobes and can replace an entire thyroid gland. Thyroid C-cell neoplasms in bulls, other animal species, and human beings are firm, and in some areas the stroma consists of dense bands of fibrous connective tissue. Multiple metastases occur in the cranial cervical lymph nodes (Fig. 12-46). These nodes are usually large and have areas of necrosis and hemorrhage. Pulmonary metastases appear as discrete tan nodules and occur infrequently. C-cell carcinomas are composed of neoplastic cells that are more pleomorphic than cells of adenomas. The carcinomatous cells are poorly differentiated, polyhedral to spindle-shaped, and have pale eosinophilic, finely granular, indistinct cytoplasm.

727

**Fig. 12-46 C-cell carcinoma and metastases, thyroid and cervical lymph nodes, Holstein bull.** Note the swellings in the neck (arrows) as a result of lymphadenopathy of the cranial cervical lymph nodes from metastases. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

Ultimobranchial neoplasms in the thyroid glands of bulls often have a more complex histologic structure than the typical C-cell (medullary) carcinoma in human beings, dogs, horses, and many strains of laboratory rats. The neoplasm is composed of differentiated C cells arranged as focal accumulations of neoplastic cells with abundant pale eosinophilic cytoplasm, either within the wall of the thyroid and ultimobranchial follicles or present as larger solid nodules. Ultimobranchial thyroid neoplasms often are accompanied by multifocal hyperplasia of C cells in other parts of the thyroid. The neoplastic C cells often are embedded in an increased amount of hyalinized stroma, and there are deposits of amyloid in some neoplasms. Portions of the thyroid neoplasm in bulls that are derived from less differentiated ultimobranchial remnants consist of follicle-like structures, cysts, and tubules composed of immature small basophilic cells. These neoplasms in bulls and other species closely resemble undifferentiated or stem cells of the normal ultimobranchial body that can differentiate into both C cells and follicular cells. Thyroid follicles and cribriform structures with colloidlike material formed by cells

## Pathologic Basis of Veterinary Disease, 4th Edition

resembling differentiated follicular cells often are present in the neoplasms in close association with these more primitive ultimobranchial-derived structures. Histologically the structure of ultimobranchial neoplasms in bulls is heterogeneous and resembles a variant of thyroid carcinoma in human beings. This neoplasm, designated as an intermediate type of differentiated carcinoma, has structural and immunohistochemical characteristics of both C-cell (medullary) and follicular carcinomas.

### 12.2.6 DISORDERS OF THE PARATHYROID GLANDS

#### 12.2.6.1 DEVELOPMENTAL DISTURBANCES

##### 12.2.6.1.1 Parathyroid (Kürsteiner's) Cysts

Small cysts within the parenchyma of the parathyroid glands or in the immediate vicinity of the glands occur frequently in dogs, but only occasionally in other animal species (Fig. 12-47). Parathyroid gland cysts are usually multiloculated, lined by a cuboidal to columnar, often ciliated epithelium, and are filled with a densely eosinophilic proteinaceous material. Parathyroid gland cysts appear to develop from persistent and dilated remnants of the duct that connects the parathyroid and thymic primordia during embryonic development. Parathyroid gland cysts are distinct from midline cysts derived from remnants of the thyroglossal duct. The latter are lined by multilayered thyroidogenic epithelium that often has colloid-containing follicles and are usually located near the midline, from the base of the tongue to the mediastinum.

**Fig. 12-47 Parathyroid cyst (left), parathyroid gland, dog.** The parathyroid cyst (arrow) was formed from the persistent and distended embryonic duct that connects parathyroid-thymic primordia in the III and IV pharyngeal pouches (Kürsteiner's cyst). Besides the parathyroid cyst, both parathyroid glands (P) are hyperplastic because of chronic renal failure. T, Thyroid gland. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

728

### 12.2.6.2 HYPOPARATHYROIDISM

In hypoparathyroidism, either the parathyroid glands secrete subnormal amounts of PTH or the hormone secreted is unable to interact with target cells. Hypoparathyroidism has been recognized in dogs, particularly in smaller breeds such as schnauzers and terriers, and infrequently in other animal species. Idiopathic hypoparathyroidism in adult dogs usually is caused by a diffuse lymphocytic parathyroiditis. Other infrequent causes of hypoparathyroidism include invasion and destruction of parathyroid glands by primary or metastatic neoplasms and trophic atrophy of parathyroid glands resulting from long-term hypercalcemia. In addition, the parathyroid glands are sometimes damaged or inadvertently removed during surgery involving the thyroid glands.

The functional disturbances and clinical manifestations of hypoparathyroidism primarily are the result of increased neuromuscular excitability and tetany. Because of the lack of PTH, bone resorption is decreased and blood calcium concentrations diminish progressively to 4 to 6 mg/dl ([Fig. 12-48](#)). Affected animals are restless, nervous, ataxic, weak, and have intermittent tremors of separate muscle groups. Tremors can progress to generalized tetany and convulsive seizures. Concurrently, blood phosphorus concentrations are increased because of increased renal tubular reabsorption.

#### 12.2.6.2.1 Lymphocytic Parathyroiditis

Lymphocytic parathyroiditis is characterized by extensive degeneration of chief cells and replacement fibrosis. Mild lesions include infiltrates of lymphocytes and plasma cells and nodular hyperplasia of chief cells. Later the parathyroid gland is completely replaced by lymphocytes, fibroblasts, and neocapillaries with few remaining viable chief cells ([Fig. 12-49](#)). Lymphocytic parathyroiditis develops by an immune-mediated mechanism, as evidenced by the production of a similar destruction of parathyroid gland parenchyma and lymphocytic infiltration in dogs injected with emulsions of parathyroid gland in adjuvant.

Fig. 12-48 Schematic diagram of the alterations in serum calcium and phosphorus concentrations in response to an inadequate secretion of parathyroid hormone (PTH). A progressive increase in serum phosphorus concentration and a notable decline in the concentration of serum calcium resulted in increased neuromuscular excitability and tetany. (Redrawn with permission from Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 12.2.6.3 HYPERPARATHYROIDISM

#### 12.2.6.3.1 Primary Hyperparathyroidism: Functional Chief Cell Neoplasms

Adenomas and carcinomas of parathyroid glands often secrete excessive amounts of PTH, resulting in a syndrome of primary hyperparathyroidism. Prolonged increased secretion of PTH accelerates osteolytic and osteoclastic bone resorption. Mineral is removed from the skeleton at an accelerated rate, and bone is replaced by immature fibrous connective tissue. The lesions of fibrous osteodystrophy are generalized throughout the skeleton but are accentuated in certain areas (e.g., maxilla, mandible, and subperiosteal areas of long bones).

Adenomas of parathyroid glands are encountered in older animals, particularly dogs and infrequently in certain strains of rats, but parathyroid carcinomas are uncommon. Chief cell adenomas usually cause considerable enlargement of a single parathyroid gland. This is light brown to red and located either in the cervical region by the thyroid gland or, infrequently, within the thoracic cavity near the base of the heart. Parathyroid adenomas are encapsulated and sharply demarcated from the adjacent thyroid gland.

729

730

**Fig. 12-50 Adenoma, parathyroid gland, dog.** The adenoma consists of closely packed chief cells arranged in small groups separated by fine fibrous septa containing capillaries (*arrowheads*). It is partially encapsulated and has compressed the adjacent, nonneoplastic parathyroid tissue (*arrows*), which has undergone trophic atrophy. H&E stain. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

Parathyroid gland adenomas are composed of small, closely packed groups of chief cells delineated by delicate vascular connective tissue septa that have many capillaries (Fig. 12-50). The neoplastic chief cells

## Pathologic Basis of Veterinary Disease, 4th Edition

---

are round to polyhedral and have pale expanded eosinophilic cytoplasm in which are a few electron-dense secretory granules and prominent arrays of endoplasmic reticulum and Golgi complexes (Fig. 12-51).

The functional disturbances observed with endocrinologically active chief cell neoplasms are primarily the result of hypercalcemia and weakening of bones by excessive PTH-stimulated resorption of calcium. Cortical bone is thinned as a result of increased resorption by osteoclasts stimulated by the autonomous secretion of PTH (Fig. 12-52). Lameness can be due to fractures of long bones that occur after relatively minor physical trauma. Compression fractures occur in vertebral bodies, resulting in pressure on the spinal cord and nerves that leads to motor and/or sensory dysfunction. Facial hyperostosis due to extensive osteoblastic proliferation and deposition of poorly mineralized osteoid, and loosening or loss of teeth from alveolar sockets, has been observed in dogs with primary hyperparathyroidism. Hypercalcemia results in anorexia, vomiting, constipation, depression, polyuria, polydipsia, and generalized muscular weakness because of decreased neuromuscular excitability.

**Fig. 12-51 Adenoma, parathyroid gland, dog.** Active chief cells have large lamellar arrays of rough endoplasmic reticulum (*E*), prominent Golgi apparatus (*G*), and large mitochondria (*M*) but few secretory granules (*S*). *N*, Nucleus of chief cell. TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

**Fig. 12-52 Primary hyperparathyroidism, humerus, dog.** Severe thinning of cortical bone and large resorptive cavities (*arrow*) have resulted from localized resorption of bone by osteoclasts. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

730

The most practical laboratory test to aid in the diagnosis of primary hyperparathyroidism is quantification of the concentrations of total blood calcium, phosphorus and circulating PTH (*N*-terminal or immunoradiometric [IRMA] assay). Dogs with primary hyperparathyroidism have greatly increased blood calcium concentrations (12 to 20 mg/dl or above). Blood phosphorus concentrations are low to normal (4 mg/dl or less) due to inhibition of renal tubular phosphorus reabsorption by the autonomous secretion of PTH. The urinary excretion of calcium and phosphorus is increased and this can predispose to the development of nephrocalcinosis and urolithiasis.

731

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 12.2.6.3.2 Secondary Hyperparathyroidism

#### 12.2.6.3.2.1 Nutritional imbalances

Nutritional hyperparathyroidism occurs commonly in cats, dogs, certain nonhuman primates, horses, domestic and captive birds, and reptiles. The increased secretion of PTH is a compensatory mechanism induced by nutritional imbalances. Such imbalances occur in diets low in calcium, diets with an excess of phosphorus, and diets with normal or low content of calcium and in New World primates housed indoors and fed diets with inadequate amounts of vitamin D<sub>3</sub>. The significant result is hypocalcemia, which stimulates the parathyroid glands. Blood phosphorus concentrations, when elevated, contribute indirectly to parathyroid stimulation by decreasing blood calcium.

In response to the diet-induced hypocalcemia, chief cells undergo hypertrophy and hyperplasia with increased amounts of lightly eosinophilic or vacuolated cytoplasm. The organelles involved with protein synthesis (endoplasmic reticulum) and packaging of secretory products (Golgi apparatus) are well developed. Many chronically stimulated chief cells with well-developed secretory organelles accumulate glycogen after 5 to 14 weeks.

The most frequent nutritional imbalance causing hyperparathyroidism is the ingestion of excessive amounts of phosphorus. Hyperphosphatemia stimulates the parathyroid gland indirectly by lowering blood calcium. Horses that develop the disease usually have been fed grain diets with below-average-quality roughage. Evidence of excessive phosphorus intake might be difficult to determine, as the excess phosphorus could have been supplied as a bran supplement to the grain ration. The disease in horses is commonly referred to as “big head” because of the fact that the fibrous osteodystrophy is typically hyperostotic and most severe in the mandible and maxilla (see [Fig. 16-57](#)). The diet is usually palatable and nutritious except for its excessive phosphorus and marginal or deficient calcium content. A diet deficient in calcium fails to supply the daily calcium requirement, and hypocalcemia develops even though a greater proportion of calcium ingested is absorbed. Changes in concentrations of calcium and phosphorus in urine are more consistent and useful in the clinical diagnosis of nutritional secondary hyperparathyroidism in horses than changes in blood concentrations of these minerals. The increased secretion of PTH acts on normal kidneys to notably increase urinary phosphorus excretion and to decrease calcium loss in the urine.

#### 12.2.6.3.2.2 Renal disease

Hyperparathyroidism as a complication of chronic renal failure is characterized by excessive production of PTH in response to chronic hypocalcemia. When the renal disease is extensive enough to reduce the glomerular filtration rate, phosphorus is retained and hyperphosphatemia develops. The increased blood phosphorus concentration depresses ionized blood calcium concentration, resulting in parathyroid gland stimulation. Chronic renal disease also impairs the production of 1,25-(OH)<sub>2</sub>D<sub>3</sub> by the kidneys, thereby diminishing intestinal calcium transport and increasing mobilization of calcium from the skeleton. All parathyroid glands undergo notable chief cell hyperplasia, and the bones subsequently develop varying degrees of generalized fibrous osteodystrophy. The fibrous osteodystrophy that occurs with chronic renal failure is also most severe in the skull, but it is usually osteoporotic. Affected animals, especially dogs, have supple mandibles and/or maxillas known as “rubber jaws” (see [Fig. 16-57](#)).

### 12.2.6.4 PSEUDOHYPERPARATHYROIDISM: HUMORAL HYPERCALCEMIA OF MALIGNANCY

Hypercalcemia in animals is a common disorder with many causes. The most common form is cancer-associated hypercalcemia or humoral hypercalcemia of malignancy (HHM). Notable increases in serum calcium concentration resulting from an imbalance of calcium released from bones, excreted by the kidneys, or absorbed from the intestinal tract are reported with apocrine gland adenocarcinomas, metastases of solid neoplasms to bone, and hematologic malignancies, such as lymphosarcoma.

The clinical signs of hypercalcemia are similar regardless of the underlying cause and depend on the rapidity of onset of increased concentrations of serum ionized calcium. Animals with total serum calcium values in excess of 16 mg/dl (4 mmol/L) generally have the most severe clinical signs. Exceptions to this rule occur, and some animals with severe hypercalcemia have only mild clinical signs. Horses and rabbits have normal total serum calcium concentrations greater than those found in other domestic animals, which should be considered before hypercalcemia is diagnosed in these species. Metabolic acidosis enhances the severity of clinical signs because it results in an increase in the ionized fraction of serum calcium. Increased serum ionized calcium induces clinical signs relating to the gastrointestinal, neuromuscular, cardiovascular, and renal systems.

731

732

The parathyroid glands in animals with HHM are small and difficult to locate or undetectable grossly. The parathyroid glands respond to the persistent cancer-associated hypercalcemia by trophic atrophy. Atrophic parathyroid glands in dogs are characterized by narrow cords of inactive chief cells with an abundant fibrous connective tissue stroma and widened perivascular spaces. Thyroid C cells undergo either diffuse or nodular hyperplasia in response to the persistent elevation in blood calcium.

Renal calcification has been detected microscopically in approximately 90% of dogs with HHM caused by anal sac apocrine gland adenocarcinomas, particularly when the calcium  $\times$  phosphorus product is  $\geq 50$ . Tubular calcification is most pronounced near the corticomedullary junction but is also present in cortical and inner medullary tubules, Bowman's capsule, and glomerular tufts. Calcification also occurs in the fundic gastric mucosa and endocardium.

Excessive secretion of biologically active PTH-rP plays a central role in the pathogenesis of hypercalcemia in most forms of HHM; however, cytokines—such as interleukin-1 (IL-1), tumor necrosis factor- $\alpha$ , transforming growth factor (TGF)- $\alpha$  and TGF- $\beta$  or 1,25-dihydroxyvitamin D—can have synergistic or cooperative actions with PTH-rP. Before PTH-rP was identified, it was well understood that nonparathyroid neoplasms and humoral hypercalcemia of malignancy induced a syndrome that mimicked primary hyperparathyroidism because of secretion of a PTH-like factor that was antigenically unrelated to PTH. Purification of the substance with PTH-like activity from the adenocarcinoma derived from apocrine glands of the anal sac in dogs and multiple human neoplasms with documented HHM resulted in the discovery of PTH-rP. PTH-rP also can be demonstrated by immunohistochemical and biochemical analysis in a number of tissues, where it appears to function primarily as a paracrine factor.

#### 12.2.6.4.1 Apocrine Gland Adenocarcinoma

A syndrome of HHM in aged, primarily female dogs with adenocarcinomas derived from apocrine glands of the anal sac has been characterized. These dogs have persistent hypercalcemia (mean 16.2 mg/dl) and often mild hypophosphatemia, both of which return to normal following surgical excision of the neoplasm. The hypercalcemia persists after removal of the parathyroid glands, suggesting that the humoral

## Pathologic Basis of Veterinary Disease, 4th Edition

factor produced by neoplastic cells does not stimulate an increased secretion of PTH. Increased circulating concentrations of PTH-rP have been observed in hypercalcemic dogs with anal sac apocrine gland adenocarcinomas. The neoplasms are malignant and most have metastasized to regional lumbar aortic lymph nodes at the time of initial presentation. Clinical signs include generalized muscular weakness, anorexia, vomiting, bradycardia, depression, polyuria, and polydipsia. These signs are primarily the result of severe hypercalcemia.

Apocrine gland adenocarcinomas develop as firm, usually unilateral masses, ventrolateral to the anus and close to the anal sac but not attached to the overlying skin (Fig. 12-53). The neoplasm arises in the wall of the anal sac and projects as a variably sized mass into the lumen (Fig. 12-54).

This adenocarcinoma forms glandular acini into whose lumens papillary projections of apical cytoplasm extend (Fig. 12-55). It is histologically distinct from the more common perianal (circumanal) gland tumor, which arises in hepatoid glands. The majority of neoplasms histologically contain glandular and solid areas. The solid pattern is characterized by sheets, microlobules, and packets separated by a thin fibrovascular stroma. Pseudorosettes are common in solid areas adjacent to small blood vessels.

12.2.6.4.2

### Neoplasms Metastatic to Bone

Solid neoplasms that metastasize widely to bone and grow locally can produce hypercalcemia by inducing local bone resorption. This is not common in animals but is an important cause of HHM in human beings, particularly patients with metastatic breast and lung carcinomas.

732

733

**Fig. 12-53 Adenocarcinoma, apocrine glands of right anal sac, anus, dog.** The right perianal region is distended by a small adenocarcinoma (*arrow*), which has compressed the right side of the anus. It also projects, as two nodules, on the dorsolateral margin of the anus. *T, Tail.* (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The pathogenesis of enhanced bone resorption is not well understood, but the two primary mechanisms include (1) secretion of cytokines or factors that stimulate local bone resorption, and (2) indirect stimulation of bone resorption by tumor-induced cytokine secretion from local immune or bone cells. Cytokines or factors that are secreted by neoplastic cells and stimulate local bone resorption include PTH-rP, TGF- $\alpha$  and TGF- $\beta$ , and prostaglandins, especially prostaglandin E<sub>2</sub>.

12.2.6.4.3

### Lymphosarcoma

Lymphosarcoma is the most common neoplasm associated with hypercalcemia in dogs and cats. Estimates of the prevalence of hypercalcemia in dogs with lymphosarcoma vary from 20% to 40%. Peripheral lymph node enlargement is present in some cases; cranial mediastinal or visceral nodes usually are involved. The hypercalcemia results from the production of humoral substances by neoplastic cells and/or from physical disruption of trabecular bone by lymphosarcoma in bone marrow. Serum immunoreactive PTH concentrations are subnormal, and plasma prostaglandin E<sub>2</sub> concentrations are not different from those of controls.

Most dogs with lymphoma and HHM have significantly increased circulating PTH-rP concentrations, but these concentrations are lower (2 to 15 pmol) than in dogs with carcinomas and HHM; there is no correlation with serum calcium concentration. The latter indicates that PTH-rP is an important marker in dogs with HHM and lymphoma but is not the sole humoral factor responsible for the stimulation of osteoclasts and development of hypercalcemia. It is likely that cytokines such as IL-1 or tumor necrosis factor function synergistically with PTH-rP to induce HHM in dogs with lymphoma. Some dogs and human patients with lymphoma and hypercalcemia have increased serum 1,25-dihydroxyvitamin D concentrations that could be responsible for or contribute to the induction of hypercalcemia. PTH (*N*-terminal) concentrations in dogs with lymphoma and hypercalcemia usually are in the normal range; however, a few dogs have concentrations increased slightly above the normal range.

12.2.6.5

### PARTURIENT HYPOCALCEMIA

Parturient paresis in dairy cattle is a complex metabolic disease characterized by the development of severe hypocalcemia and hypophosphatemia near the time of parturition and the initiation of lactation. The serum calcium concentration decreases to less than 50% of normal in spite of an increased secretion of PTH by the cow's parathyroid glands. Bone resorption remains minimal and few osteoclasts are present on bone surfaces. Biochemical and ultrastructural studies in cows indicate that the parathyroid glands are capable of responding to the acute hypocalcemia by increasing development of the cellular organelles responsible for hormonal synthesis and by increasing secretion of PTH.

733

The composition of the diet fed to dairy cows is a significant factor in the pathogenesis of parturient hypocalcemia. Diets with excessive calcium have been incriminated as significantly increasing the incidence of the disease. Conversely, diets low in calcium or diets supplemented with therapeutic doses of vitamin D reduce the incidence of parturient hypocalcemia. Calcium homeostasis in pregnant cows fed an excessive calcium diet appears to be maintained principally by intestinal calcium absorption (Fig. 12-56). This greater reliance on intestinal absorption rather than on PTH-stimulated bone resorption probably is a significant factor in the more frequent development of profound hypocalcemia near parturition in cows fed excessive calcium prepartal diets.

734

## Pathologic Basis of Veterinary Disease, 4th Edition

An increased prepartal secretion of calcitonin in cows that develop parturient hypocalcemia or milk fever, especially those fed excessive calcium diets, could be a factor contributing to the inability of increased PTH concentrations to mobilize calcium rapidly from skeletal reserves, and to maintain blood calcium concentrations during the critical periparturient period. The thyroidal content of calcitonin is reduced, many C cells are degranulated, and plasma concentrations of calcitonin often are increased in cows before the development of profound hypocalcemia.

**Fig. 12-56 Schematic diagram of calcium homeostasis in cows fed a high-calcium prepartal diet.** In this case, calcium homeostasis is primarily dependent on intestinal calcium absorption. The rate of bone resorption is low, and parathyroid glands are inactive. Anorexia and gastrointestinal stasis that often occur near parturition interrupt the major inflow of calcium into the extracellular fluid calcium pool. Outflow of calcium with the onset of lactation exceeds the rate of inflow into the calcium pool, and cows develop a progressive hypocalcemia and paresis. *CT*, Calcitonin; *PTH*, parathyroid hormone. (Redrawn with permission from Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

### 12.2.7 DISORDERS OF PANCREATIC ISLET CELLS

#### 12.2.7.1 HYPOFUNCTION OF PANCREATIC ISLET CELLS: DIABETES MELLITUS

Diabetes mellitus is a metabolic disorder that results from a reduction of insulin available for normal function of many cells in the body. In some cases, increased concentrations of glucagon contribute to development of persistent hyperglycemia. Insulin unavailability could be due to degenerative changes in  $\beta$  cells of the pancreatic islets, reduced effectiveness of the hormone because of the formation of antiinsulin

## Pathologic Basis of Veterinary Disease, 4th Edition

---

antibodies or inactive complexes, damage to  $\beta$  cells from immune-mediated islet cytotoxicity, or inappropriate secretion of hormones by neoplasms in other endocrine organs.

Diabetes mellitus is a common endocrinopathy in dogs, with a reported incidence of 1:200. Most cases of spontaneous diabetes occur in mature dogs and in females approximately twice as often as males. An increased incidence of diabetes mellitus has been observed in certain small breeds of dogs, such as miniature poodles, dachshunds, and terriers, but nearly all breeds of dogs can be affected.

Development of diabetes mellitus in young dogs is the result of idiopathic atrophy of the pancreas, acute pancreatitis with necrosis and hemorrhage, and aplasia of pancreatic islets. The pancreas with idiopathic atrophy is reduced to a third or less of its size. Hypoplasia of pancreatic islets in which the islets are absent but the pancreatic acini and ducts are present and functional has been a cause of diabetes mellitus in young dogs (2 to 3 months of age).

In the pathogenesis of diabetes mellitus, several factors are responsible for the decreased availability of insulin. Destruction of islets secondary to severe pancreatitis or the selective degeneration of islet cells are the most common causes in animals. In dogs, the pancreatic islets are often destroyed because of inflammation of the exocrine pancreas. Chronic relapsing pancreatitis with progressive loss of both exocrine and endocrine cells and replacement by fibrous connective tissue is a frequent cause of diabetes mellitus. In these dogs, the pancreas becomes firm, multinodular, and has scattered areas of hemorrhage and necrosis after a recent relapse (Fig. 12-57). Later in the course of the disease, all that remains of the pancreas is a thin fibrous band or nodule near the duodenum and stomach (Fig. 12-58).

Histologically,  $\beta$  cells are reduced in number and remaining cells have vacuolated cytoplasm (Fig. 12-59). The cytoplasm of  $\beta$  cells is distended by massive amounts of glycogen particles (Fig. 12-60). Hydropic degeneration with glycogen accumulation, especially in cats, appears to develop in  $\beta$  cells in response to long-term overstimulation or exhaustion because of peripheral insulin resistance. When disease is chronic, the islets are difficult to find. Immune-mediated isletitis characterized by a progressive lymphoplasmacytic infiltration and selective destruction of  $\beta$  cells of the islets is another cause of diabetes mellitus (type 1) in human beings, rodent models, and occasionally in dogs.

734

735

**Fig. 12-57 Chronic relapsing pancreatitis, pancreas and duodenum, cross section, dog.** The pancreas is multinodular and firm with areas of hemorrhage (*arrow*), fibrosis, and necrosis. *D*, Duodenum. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

**Fig. 12-58 Chronic pancreatitis, pancreas, dog.** The pancreas (*P*) is markedly atrophied and its parenchyma almost completely replaced by fibrous connective tissue in “end-stage” pancreatitis. *D*, Duodenum. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

Another common pancreatic change in cats with diabetes is the selective deposition of amyloid in islets, resulting in degenerative changes in  $\alpha$  cells and  $\beta$  cells (Fig. 12-61). Scattered amyloid deposits in pancreatic

## Pathologic Basis of Veterinary Disease, 4th Edition

---

islets that increase progressively with age occur in the pancreatic islets of many cats without clinically apparent diabetes mellitus. Islet amyloid polypeptide (IAPP) (37 amino acids) and insulin are both secreted by  $\beta$  cells. The IAPP in cats, human beings, nonhuman primates, and raccoons has a unique amino acid sequence (amino acids 25 to 28: alanine, isoleucine, leucine, and serine), which is predisposed to polymerization and accumulation in pancreatic islets. As the insoluble amyloid fibers progressively accumulate in the islets, they disrupt  $\beta$  cells and surround islet capillaries, leading to the subsequent degeneration of islet cells.

**Fig. 12-59 Hydropic (“vacuolar”) degeneration, pancreatic islet, cat.**

TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

Complete expression of the complex metabolic disturbances in diabetes mellitus appears to be the result of a bihormonal abnormality. Although a relative or absolute deficiency of insulin action in response to a rising extracellular glucose concentration has been long recognized as the sine qua non of diabetes mellitus, the importance of an absolute or relative increase of glucagon secretion in some forms of the disease in certain species has been appreciated only recently. Hyperglucagonemia in diabetic patients can be the result of increased secretion of pancreatic glucagon, enteroglucagon, or both. An increased blood glucagon concentration contributes to the severe endogenous hyperglycemia by mobilizing hepatic stores of glucose and to the development of ketoacidosis by increasing the oxidation of fatty acids by hepatocytes. The major glucoregulatory consequence of insulin deficiency is reduction in the movement of glucose into insulin-sensitive tissues (e.g., liver, adipose tissue, and muscle), with a corresponding increase in hepatic glucose production, resulting in notable endogenous hyperglycemia.

**Fig. 12-61 Amyloidosis, pancreatic islets, cat.** Note the deposits of amyloid (A) and degeneration and loss of islet cells. H&E stain. (*Courtesy College of Veterinary Medicine, University of Illinois.*)

The onset of diabetes mellitus is insidious, and the clinical course is often chronic. Clinically, dogs with diabetes mellitus exhibit polydipsia, polyuria, weight loss in spite of polyphagia, bilateral cataracts, and weakness. The disturbances in water metabolism primarily have an osmotic basis. In dogs with persistent hyperglycemia and glycosuria, the renal tubular epithelium is unable to concentrate the urine effectively against the osmotic attraction of the glucose in the glomerular filtrate.

Diabetic animals have diminished resistance to bacterial and fungal infections, and diseases such as suppurative cystitis, prostatitis, bronchopneumonia, and dermatitis often become chronic or recurrent. This increased susceptibility to infection in patients with poorly controlled diabetes can be related in part to impaired chemotactic, phagocytic, and microbicidal functions and decreased adherence of polymorphonuclear leukocytes. The impaired microbicidal function of leukocytes can have a metabolic basis resulting from diminished production of cellular energy from glucose. Radiographic evidence of emphysematous cystitis is strongly suggestive of diabetes mellitus. Infections of the urinary bladder with glucose-fermenting organisms, such as *Proteus* sp., *Aerobacter aerogenes*, and *Escherichia coli* result in gas formation in the wall and lumen. Emphysema also develops in the wall of the gallbladder in some diabetic dogs.

Hepatomegaly occurs as a result of fatty degeneration. Lipids accumulate in the liver as the result of increased lipid mobilization, and hepatocytes injured by ketonemia have decreased usage of lipids. Individual hepatocytes are greatly enlarged by multiple droplets of lipid (Fig. 12-62). If the accumulation of

## Pathologic Basis of Veterinary Disease, 4th Edition

lipids is extensive and long-standing, cirrhosis develops. The liver remains enlarged, and its surface becomes coarsely nodular because of extensive remodeling of hepatic parenchyma (Fig. 12-63). Individual hepatocytes degenerate and are replaced by regenerative and hyperplastic nodules and interlobular fibrosis. Icterus and bilirubinuria often accompany severe cirrhosis.

**Fig. 12-62 Fatty degeneration, liver, dog.** The cytoplasm contains multiple large lipid droplets (*L*) that have displaced the nucleus (*N*) peripherally and compressed cytoplasmic organelles, such as mitochondria (*M*). TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

736

**Fig. 12-63 Cirrhosis, liver, diaphragmatic surface, dog.** All lobes of the liver are considerably firm and have a coarsely nodular surface. The nodules (*arrows*) represent areas of regenerative hyperplasia of hepatocytes. (*Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.*)

**Fig. 12-64 Diabetes mellitus, eyeball, lens, dog.** Early stellate lesion (*arrowheads*) along the sutures of the lens. In dogs (not in cats), cataracts (stellate lesions) can occur in poorly regulated diabetes mellitus, because glucose is metabolized in the lens by a sorbitol pathway, which leads to edema of the lens. (*Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.*)

Cataracts often develop in dogs with poorly controlled diabetes mellitus. They are stellate or asteroid in shape (Fig. 12-64) and initially appear along the suture lines of lenticular fibers. Cataract formation in the diabetic patient is related to the unique sorbitol pathway by which glucose is metabolized in the lens. Glucose is first converted to sorbitol by the enzyme aldose reductase and, subsequently, to fructose by sorbitol dehydrogenase. These sugar alcohols accumulate within the lens and result in an intracellular accumulation of solute and hypertonicity. The initial structural change in the lens consists of swelling and hydropic degeneration of lenticular fibers. In long-standing cases of diabetes mellitus, swelling of lenticular fibers continues until the majority of lenticular fibers are affected. Later, macromolecular aggregation or precipitation of normally translucent lenticular proteins develops, accompanied by disruption of lenticular fibers and formation of interfibrillar clefts. The result is diffuse, often bilateral lens opacity observed in animals with chronic diabetes mellitus.

Other extrapancreatic lesions of diabetes mellitus such as chronic renal disease, blindness, and gangrene are the result of microangiopathy characterized by thickening of the capillary basement membrane. Dogs with long-standing, poorly controlled, spontaneous diabetes mellitus develop nodular or diffuse glomerulosclerosis characterized by PAS-positive fibrillar deposits of glycoprotein, which occasionally form spherical nodules in the glomerular capillary tufts. Other renal lesions include accumulation of glycogen within cells of Henle's loop (intracytoplasmic) and distal convoluted tubule (intranuclear) (Fig. 12-65).

### 12.2.7.2 HYPERFUNCTION OF PANCREATIC ISLET CELLS

#### 12.2.7.2.1 $\beta$ -Cell (Insulin-Secreting) Neoplasms (Insulinomas)

The neoplasms most frequently arising in pancreatic islets are adenomas and carcinomas derived from  $\beta$  cells. These neoplasms are often endocrinologically active and produce dramatic functional disturbances.

Other pancreatic neoplasms appear to be derived from multipotential ductal epithelial cells that differentiate into one of several other cell types in the pancreatic islets.  $\beta$ -Cell neoplasms are seen most frequently in dogs 5 to 12 years of age (mean 9 years). These neoplasms also occur in older cattle and can cause periodic convulsions. Carcinomas of the pancreatic islets are more common than adenomas in dogs and are commonly found in the duodenal (right) lobe of the pancreas. Carcinomas of the pancreatic islets can be differentiated grossly from adenomas by their larger size, multilobular appearance, extensive invasion of adjacent parenchyma and lymph vessels, and metastases to extrapancreatic sites, such as regional lymph nodes (e.g., duodenal, mesenteric, hepatic, and splenic), liver, mesentery, and omentum.

**Fig. 12-65 Glycogen “nephrosis,” diabetes mellitus, kidney, dog.** The radially arranged light areas in the inner cortex of the kidney (*arrow*) represent tubules with abnormal accumulations of glycogen. (*Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.*)

The clinical alterations observed with functional  $\beta$ -cell neoplasms are the result of excessive insulin secretion and the development of severe hypoglycemia. The clinical signs are not specific for the hyperinsulinism produced by  $\beta$ -cell neoplasms. Initial signs include weakness, fatigue after vigorous exercise, generalized muscular twitching and weakness, ataxia, mental confusion, and changes in temperament. Dogs are easily agitated and have intermittent periods of excitability and restlessness. Periodic convulsive seizures of the tonic-clonic type occur later in the disease and increase progressively in frequency and intensity.

The predominance of clinical signs relating to the CNS demonstrates the primary dependence of the brain on glucose metabolism for energy. The failure to recognize dogs with functional islet cell neoplasms when they have clinical signs suggestive of primary disease of the nervous system has frequently led to the misdiagnoses of idiopathic epilepsy, brain neoplasm, or other organic neurologic disease. Repeated episodes of prolonged and severe hypoglycemia result in neuronal necrosis and permanent neurologic disability with terminal coma and eventually death.

Adenomas of the  $\beta$  cells of the pancreatic islets typically exist as single, yellow to dark red, small (1 to 3 cm), spherical nodules. The neoplasms are of similar consistency to or slightly firmer than that of the surrounding pancreas. Adenomas occur as a single nodule or less often as multiple nodules in one or both lobes and/or body of the pancreas. Islet cell adenomas are sharply delineated and surrounded by a thin capsule of fibrous connective tissue ([Fig. 12-66](#)). Small nests of acinar epithelial cells are sometimes present throughout the neoplasm, but are more common at the periphery. Numerous connective tissue septa containing small capillaries radiate from the capsule into the neoplasm and subdivide the neoplasm

## Pathologic Basis of Veterinary Disease, 4th Edition

into small lobules or packets. Well-differentiated neoplastic cells are round to polyhedral with distinct cell borders and pale eosinophilic, finely granular cytoplasm.

Fig. 12-66  **$\beta$ -Cell adenoma, pancreatic islet, dog.** A solid islet adenoma, surrounded by a fibrous capsule of variable thickness has compressed the adjacent exocrine pancreas (arrow). H&E stain. (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

Fig. 12-67  **$\beta$ -Cell carcinoma, pancreatic islet, dog.** The whitish-red carcinoma (CA) is well demarcated from the lobular exocrine pancreas (P). (Courtesy Dr. C. Capen, College of Veterinary Medicine, The Ohio State University.)

Islet cell carcinomas are consistently larger than adenomas, are multilobular, and invade into and through the fibrous capsule of the pancreas (Fig. 12-67). The dense bands of fibrous tissue that course through the neoplasm give rise to fine connective tissue septa containing capillaries that subdivide the neoplasm into small cords or lobules. Well-differentiated neoplastic cells in islet cell carcinomas are closely packed but are less uniform in size and shape than the cells in adenomas. They are round to polyhedral and have a granular eosinophilic cytoplasm. Mitotic figures are infrequent. Microscopic evidence of distinct local tissue invasion is the principal criterion for the diagnosis of islet cell carcinoma.

738

739

Cells composing functional islet cell neoplasms in dogs usually have histochemical and immunohistochemical characteristics of  $\beta$  cells. Ultrastructurally the neoplastic  $\beta$  cells are electron dense because of numerous cytoplasmic organelles.

### 12.2.7.2.2

#### Non- $\beta$ (Gastrin-Secreting) Islet Cell Neoplasms (Gastrinomas)

Gastrin-secreting, non- $\beta$  islet cell neoplasms of the pancreas have been reported in human beings, dogs, and cats. The hypersecretion of gastrin in human beings results in the well-documented Zollinger-Ellison syndrome, consisting of hypersecretion of gastric acid and recurrent peptic ulceration in the gastrointestinal tract. The non- $\beta$  islet cell neoplasms derived from ectopic APUD (*amine precursor uptake decarboxylase*) cells in the pancreas produce an excess of gastrin, which normally is secreted by cells of the antral and duodenal mucosa. The incidence of gastrin-secreting pancreatic neoplasms in dogs and cats is uncertain, but it appears to be uncommon compared with that of insulin-secreting  $\beta$ -cell neoplasms. In the comparatively few canine and feline cases studied, the clinical signs have included anorexia, vomiting of blood-tinged material, intermittent diarrhea, progressive weight loss, and dehydration, the result of the multiple ulcerations of the gastrointestinal mucosa because of gastrin-stimulated gastric acid hypersecretion (Zollinger-Ellison-like syndrome).

Animals with Zollinger-Ellison-like syndrome have single or multiple, variably sized neoplasms in the pancreas. These are firm, have increased amounts of fibrous connective tissue, and although partially encapsulated, the neoplasm usually extends into the surrounding pancreas.

Three histologic patterns of gastrin-secreting islet neoplasms in dogs are recognized: (1) the ribbon or trabecular pattern, (2) solid nests of cells with a delicate, highly vascularized stroma, and (3) an acinar pattern with cuboidal neoplastic cells arranged around a central lumen. The stroma is prominent and hyalinized in some gastrin-secreting neoplasms.

Canine gastrin-secreting islet cell neoplasms invade locally into the adjacent pancreas and often metastasize to regional lymph nodes and to the liver. These dogs have either single or multiple ulcerations of the gastric and/or duodenal mucosa, and blood in the gut lumen.

Other non- $\beta$  islet cell neoplasms reported in animals are those of glucagon-secreting  $\alpha$  cells. Glucagonomas have been reported rarely in dogs and are associated with superficial necrolytic dermatitis.

---

### 12.2.8 DISORDERS OF THE PINEAL GLAND

#### 12.2.8.1 PINEALITIS

Pinealitis accompanying uveitis is well established in animal models of experimental autoimmune uveoretinitis following immunization with retinal antigens. Because the pineal gland is rarely, if ever, histologically examined during active uveitis in human beings with autoimmune uveitis, there is no direct evidence of concurrent pineal pathology, but it is suspected. However, there are reports documenting lymphocytic and eosinophilic pinealitis in horses with recurrent uveitis.

#### 12.2.8.2 PINEAL TUMORS

Pineal tumors are exceedingly rare in both human beings and animals. The majority of cases in domestic animals involve laboratory rats, but there are isolated reports in a cow, goat, horse, cockatiel, and chicken. Tumors are classified as well-differentiated pinealocytomas, anaplastic pinealoblastomas, or mixed tumors. Immunoreactivity to synaptophysin has been shown to be the most consistent marker for pineal tumors.

### 12.2.9 DISORDERS OF THE CHEMORECEPTOR ORGANS

#### 12.2.9.1 NEOPLASMS

Although chemoreceptor tissue appears to be widely distributed in the body, neoplasms develop principally in the aortic and carotid bodies. Aortic body chemodectomas are encountered more frequently in animals than those of the carotid body, but the reverse is true for human beings. These neoplasms develop primarily in dogs and infrequently in cats and cattle. Brachycephalic breeds of dogs, such as the boxer and Boston terrier, are highly predisposed to develop neoplasms of the aortic and carotid bodies.

##### 12.2.9.1.1 Neoplasms of the Aortic Body

Aortic body neoplasms appear most frequently as a single mass or as multiple nodules near the base of the heart (Fig. 12-68). They vary considerably in size (from 0.5 to 12.5 cm) with carcinomas being larger than adenomas. Solitary small adenomas either are attached to the adventitia of the pulmonary artery and ascending aorta or are embedded in the adipose connective tissue between these major vessels. They have a smooth external surface and on cross section are white and mottled with red to brown areas. Larger adenomas are multilobular and can compress and indent the wall of the atria, displace the trachea, and partially surround the major vessels at the base of the heart. Aortic body carcinomas are less frequent than adenomas in dogs. Carcinomas infiltrate the wall of the pulmonary artery and form papillary projections into its lumen or invade through the wall into the lumen of the atria. Although neoplastic cells often invade blood vessels, metastases to the lungs and liver occur infrequently in dogs.

739

740

Fig. 12-68 **Carcinoma, aortic body, dog.** Note the large mass (C) at the base of the heart (H). Contiguous portions of the right-middle and diaphragmatic lung lobes are atelectatic. L, Lungs. (Courtesy College of Veterinary Medicine, University of Illinois.)

Neoplasms of the aortic bodies in animals are not functional (i.e., they do not secrete excess hormone into the circulation), but as a space-occupying lesion they can produce a variety of functional disturbances. Larger aortic body adenomas and carcinomas put pressure on the atria, vena cava, or both and cause manifestations of cardiac decompensation. A higher percentage of aortic body neoplasms than carotid body neoplasms are benign. Aortic body carcinomas invade locally into the atria, pericardium, and adjacent vessels.

### 12.2.9.1.2

#### Neoplasms of the Carotid Body

Carotid body neoplasms arise near the bifurcation of the common carotid artery in the cranial cervical area. They are usually unilateral, only rarely bilateral, and are slow growing. Adenomas vary from approximately 1 to 4 cm in diameter, are well encapsulated, and have a smooth external surface. The bifurcation of the common carotid artery is incorporated in the mass, and neoplastic cells are firmly adhered to the tunica adventitia. Adenomas are firm, white with scattered areas of hemorrhage, and are extremely vascular.

Carotid body carcinomas are larger, more coarsely multinodular than adenomas, invade the capsule, and penetrate into the walls of adjacent blood and lymph vessels. The external jugular vein and some cranial nerves can be incorporated into the neoplasm. Metastases of carotid body carcinomas occur in approximately 30% of cases and have been found in the lungs, tracheobronchial and mediastinal lymph nodes, liver, pancreas, and kidneys. Multicentric neoplastic transformation of chemoreceptor tissue (aortic and carotid bodies) occurs frequently in brachycephalic breeds of dogs.

The microscopic features of chemoreceptor neoplasms (“chemodectomas”) are essentially similar whether they are derived from the carotid or the aortic body. The neoplasm is subdivided into lobules by

## Pathologic Basis of Veterinary Disease, 4th Edition

prominent branching trabeculae of connective tissue, which originate from the fibrous capsule. Neoplasms are further subdivided into smaller nests by fine septa of collagenous and reticulin fibers and small capillaries. Neoplastic cells are commonly aligned along and around small capillaries and are discrete, round to polyhedral, and closely packed and have pale eosinophilic, finely granular, and often vacuolated cytoplasm.

Although the cause of carotid and aortic body neoplasms is unknown, a genetic predisposition aggravated by chronic hypoxia could account for the greater risk of development in certain brachycephalic breeds, such as the boxer and Boston terrier. Carotid bodies of several mammalian species, including dogs, have developed hyperplastic foci when the animals were subjected to the chronic hypoxia of high altitude. Human beings living at high altitudes have 10 times the frequency of chemodectomas as those residing at sea level.

12.2.9.1.3

### Heart-Base Neoplasms Derived from Ectopic Thyroid Gland Tissue

Adenomas and carcinomas derived from ectopic thyroid gland account for approximately 5% to 10% of “heart-base” neoplasms in dogs. They often compress or invade structures in the cranial mediastinum near the base of the heart (Fig. 12-69). Ectopic thyroid gland neoplasms have a compact cellular (solid) pattern that is difficult to distinguish histologically from that of aortic body neoplasms. Cells of ectopic thyroid gland neoplasms generally are smaller than those of aortic body neoplasms and have more hyperchromatic nuclei and an eosinophilic cytoplasm. Thyroidal neoplasms of follicular cells are not consistently subdivided into small packets by fine strands of connective tissue. Giant cells are infrequent in ectopic thyroid gland neoplasms, and the stroma is not prominent. Usually, primitive follicular structures or colloid-containing follicles can be demonstrated in ectopic thyroid gland neoplasms, but not in aortic body neoplasms.

## 13 Chapter 13 Bone Marrow, Blood Cells, and Lymphatic System\*

MICHAEL M. FRY

M. DONALD McGAVIN

### 13.1 INTRODUCTION

#### 13.1.1 STRUCTURE AND FUNCTION

##### 13.1.1.1 BONE MARROW AND BLOOD CELLS

Hematopoiesis, the term used to describe the process through which blood cells are made, is derived from *haima* (Gr., blood) and *poiein* (Gr., to make). Hematopoiesis is synonymous with hemopoiesis. The basic concepts below provide a framework for understanding the mechanisms of injury and diseases presented later in the chapter.

##### 13.1.1.1.1 Basic Concepts

- Hematopoiesis occurs primarily in the bone marrow.
- Hematopoiesis may also occur elsewhere (extramedullary hematopoiesis), most commonly in the spleen.
- Hematopoietic tissue is highly proliferative; billions of cells per kilogram of body weight are produced each day.
- Pluripotent hematopoietic stem cells are a self-renewing population giving rise to cells with committed differentiation programs and are common ancestors of all blood cells. The process of hematopoietic differentiation is shown in [Fig. 13-1](#).
- Hematopoietic cells undergo sequential divisions as they mature, so there are higher numbers of mature than immature cells. Cells also continue to mature after they have stopped dividing. Conceptually, it is helpful to consider cells in the bone marrow as belonging to mitotic and postmitotic compartments. Examples of developing hematopoietic cells are shown in [Fig. 13-2](#).
- Mature cell types have different normal life spans, varying from hours (neutrophils), to days (platelets), to months (erythrocytes), to years (some lymphocytes).
- The hematopoietic system is under exquisite local and systemic control, and responds rapidly and predictably to various stimuli.
- Production and turnover of blood cells are balanced so that, in health, numbers are maintained within normal ranges (steady-state kinetics).

## Pathologic Basis of Veterinary Disease, 4th Edition

---

- Normally the bone marrow releases only mature cell types (and very low numbers of cells that are almost fully mature) into the circulation. In response to certain physiologic or pathologic stimuli, however, the bone marrow will release immature cells that are further back in the supply “pipeline.”

\* Previous contributions to this chapter were made by Dr. G.P. Searcy, Western College of Veterinary Medicine, University of Saskatchewan.

### 13.1.1.1.2 Development of Bone Marrow and Blood Cells

Hematopoiesis is first evident as blood islands in the embryonic yolk sac. During gestation, the bulk of hematopoiesis shifts from the yolk sac to the liver and spleen, and eventually to the bone marrow. The distribution of hematopoietic cells changes with age. The general pattern is that hematopoietically active tissue (red marrow) regresses and is replaced with hematopoietically inactive tissue, mainly fat (yellow marrow). Thus, in newborns and very young animals, the bone marrow consists largely of hematopoietically active tissue, with relatively little fat. In adults, hematopoiesis occurs primarily in the pelvis, sternum, ribs, vertebrae, and the proximal ends of humeri and femora. Even within these areas of active hematopoiesis, fat may constitute a significant proportion of the marrow volume.

### 13.1.1.1.3 Structure and Function of Bone Marrow and Blood Cells

#### 13.1.1.1.3.1 Hematopoietic microenvironment

Hematopoietic cells, supporting connective tissue cells, extracellular matrix components, and soluble factors form the bone marrow hematopoietic microenvironment. There is complex functional interplay among these components. Behavior of hematopoietic cells is influenced by direct cell-to-cell and cell-matrix interactions and by soluble mediators, such as cytokines and hormones, that interact both with cells and with matrix proteins. Cells localize to specific niches within the hematopoietic microenvironment via adhesion molecules, such as integrins, immunoglobulins (Igs), lectins, and other receptors, that recognize ligands on other cells or matrix components. Cells also express receptors for soluble molecules, such as chemokines (chemoattractant cytokines) and hormones, that influence cell trafficking and metabolism.

743

744

**Fig. 13-1 Schematic illustration of the hematopoietic hierarchy in the bone marrow.** The bone marrow consists of: (1) stem cells, pluripotent cells capable of self-renewal; (2) committed progenitor cells (myeloid and lymphoid progenitor cells); and (3) maturing cells. Maturing cells develop from cells called colony-forming units (CFUs). The myeloid stem cell gives rise to CFUs responsible for the regeneration of red blood cells (erythroid CFUs), platelets (megakaryocyte CFUs), basophils (basophil CFUs), and eosinophils (eosinophil CFUs). Monocytes and neutrophils are derived from a common committed progenitor cell (granulocyte-macrophage CFU). The lymphoid progenitor cell generates the B-lymphocyte progeny in the bone marrow and T-lymphocyte progeny in the thymus. (From Kierszenbaum AL: Histology and cell biology: an introduction to pathology, St Louis, 2002, Mosby.)

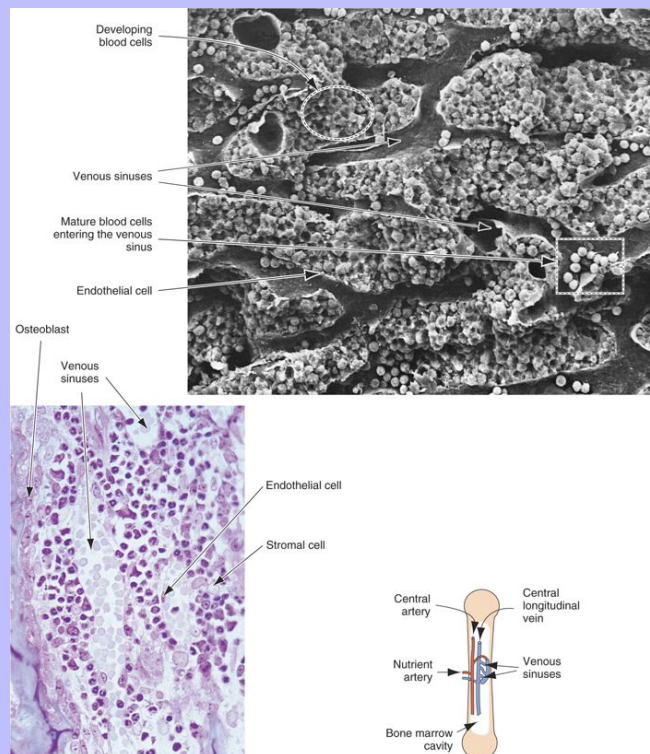

Fig. 13-2 **Normal hematopoiesis**, canine bone marrow aspirate. *ESE*, Early stage erythroid; *ESM*, early stage myeloid; *LSE*, late stage erythroid; *LSM*, late stage myeloid. Wright's stain. (Courtesy Dr. M.M. Fry, College of Veterinary Medicine, University of Tennessee.)

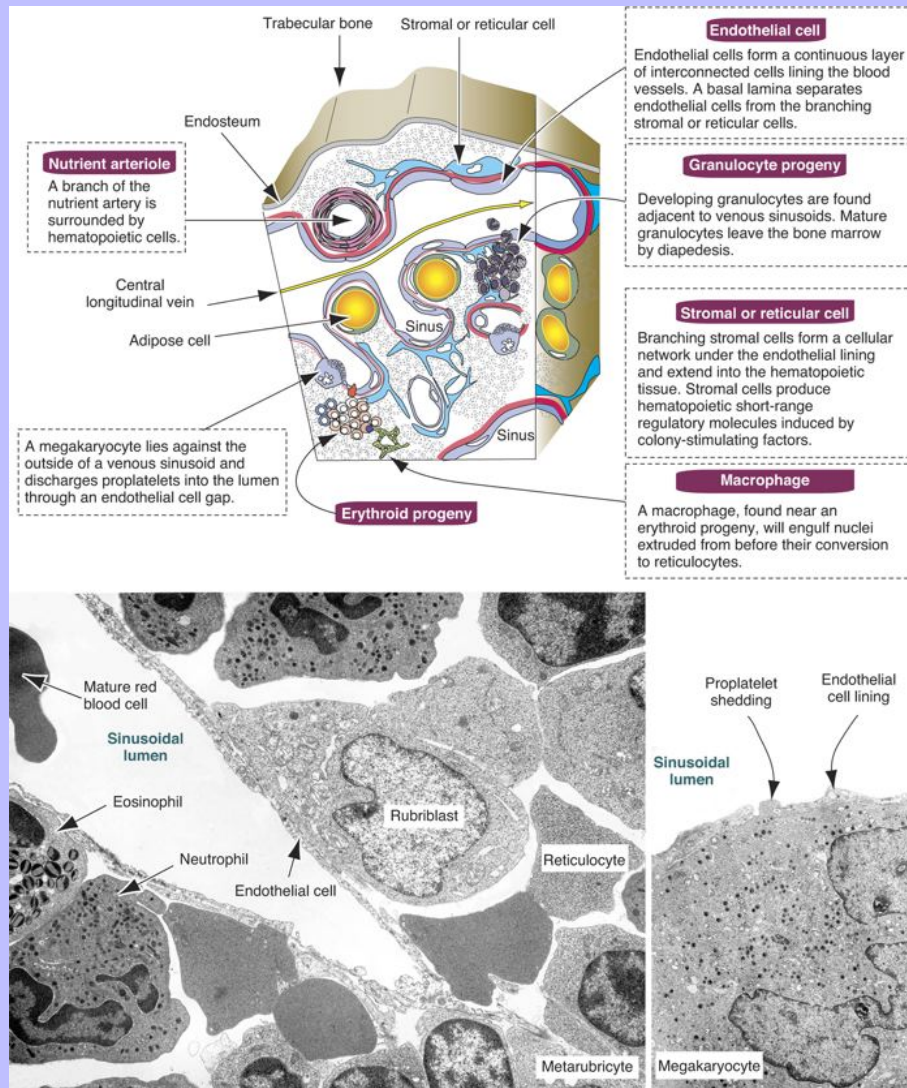

The marrow cavity is interlaced with venous sinuses composed of a luminal layer of specialized endothelial cells and an abluminal layer of specialized fibroblasts known as adventitial reticular cells (Figs. 13-3 and 13-4). Hematopoiesis takes place in the compartment (hematopoietic spaces) between these venous sinuses. Sinusoidal endothelial cells perform a barrier function and regulate traffic of chemicals and particles between the intravascular and extravascular spaces. Reticular cells send cytoplasmic processes into the hematopoietic spaces, forming a scaffold that supports the hematopoietic cells. Adipocytes are a major component of marrow tissue. As discussed previously, the amount of fat increases with age, particularly in the long bones. Osteoblasts, osteoclasts, and elongated flat cells line the endosteum. Stromal cells, presumably of fibroblast origin, provide structural support and produce extracellular matrix components, such as proteoglycans, glycosaminoglycans, collagen, fibronectin, and others. Macrophages, lymphocytes, and plasma cells are also components of the hematopoietic microenvironment.

**Fig. 13-3 Schematic illustration of the bone marrow.** The bone marrow can be red because of the presence of hematopoietic elements, or yellow, owing to fat. Hematopoietic tissue may replace fat, or vice versa, depending on the demand for hematopoiesis. In the adult, red bone marrow is found in the skull, clavicles, vertebrae, ribs, sternum, pelvis, and ends of the long bones of the limbs. Blood vessels and nerves reach the bone marrow by piercing the bony shell. The nutrient artery enters the midshaft of a long bone and branches into central longitudinal arteries that connect with the venous sinuses. The venous sinuses empty into the central longitudinal vein, which runs parallel to the nutrient artery. The internal surface of the bone is lined by trabeculae projecting into the marrow cavity. The endosteum lines the bony surface. (From Kierszenbaum AL: Histology and cell biology: an introduction to pathology, St Louis, 2002, Mosby. Scanning electron micrograph from Kessel RG, Kardon RH: Tissues and organs, New York, 1979, WH Freeman.)

**Fig. 13-4 Schematic illustration of the bone marrow.** (From Kierszenbaum AL: Histology and cell biology: an introduction to pathology, St Louis, 2002, Mosby.)

13.1.1.1.3.2

## Regulation of hematopoiesis

Control of hematopoiesis is complex, with many redundancies, feedback mechanisms, and pathways that overlap with other physiologic and pathologic processes. Many cytokines influence cells of different lineages and stages of differentiation. The aim of this section is not to explain these regulatory pathways in detail, but rather to provide a broad overview, and thus a basic framework for understanding mechanisms of disease involving the hematopoietic system.

## Pathologic Basis of Veterinary Disease, 4th Edition

13.1.1.1.3.3

### Erythropoiesis

*Erythropoiesis*—from *erythros* (Gr., red)—refers to the production of red blood cells (RBCs), or erythrocytes, whose main function is gas ( $O_2$  and  $CO_2$ ) exchange. The dominant regulator of erythropoiesis is a glycoprotein aptly named erythropoietin (Epo). Epo acts on early erythroid progenitor cells in concert with other cytokines, including interleukins (IL-3, IL-4, IL-9), granulocyte-macrophage colony-stimulating factor (GM-CSF), and insulin-like growth factor. Epo is synthesized primarily in the kidney, and exerts its effects by promoting proliferation and inhibiting apoptosis of developing erythroid cells that express Epo receptors. The stimulus for increased Epo production is hypoxia. Because erythrocytes are packed with hemoglobin, of which iron is a component, adequate iron availability is also essential to erythropoiesis. Physiologic systems exist to conserve and recycle iron, as discussed further later.

**Fig. 13-5 Reticulocytosis, canine blood smears. A, Reticulocytes (arrows) appear polychromatophilic with routine staining. Wright's stain. B, Reticulocytes. Precipitated aggregates of RNA are stained blue with new methylene blue. (A and B, Courtesy Dr. M.M. Fry, College of Veterinary Medicine, University of Tennessee.)**

The earliest erythroid precursor identifiable by routine light microscopy is the rubriblast, which undergoes maturational division to produce 8 to 32 progeny cells. Late-stage erythroid precursors known as metarubricytes extrude their nuclei and become reticulocytes, the cells at the differentiation stage immediately preceding the mature erythrocyte. Reticulocytes start maturing in the bone marrow and finish maturing in the peripheral blood circulation and the spleen. (Horses are an exception in that they do not release reticulocytes into circulation, even in situations of increased demand.) The normal transit time from rubriblast to mature erythrocyte is on the order of approximately 1 week. Unlike mature erythrocytes, which lack organelles, reticulocytes still contain ribosomes and mitochondria, mainly to support completion of hemoglobin synthesis. These remaining organelles impart a bluish-purple cast (polychromasia) to reticulocytes on routine blood smear examination and, when stained with dye such as new methylene blue, precipitate to form irregular aggregates of dark-staining material (Fig. 13-5). Cats also release a more mature form of reticulocyte in circulation, the punctate reticulocyte, which has a much finer staining pattern when stained with new methylene blue and does not appear bluish-purple (polychromatophilic) on routine blood smear examination.

Mature erythrocytes circulate for a long time compared with other blood cells. Their mean life span varies between species: approximately 150 days in horses and cattle, 100 days in dogs, 70 days in cats. They therefore need to be highly resilient cells, built to withstand continual mechanical and biochemical stresses. In most mammalian species, erythrocytes have a biconcave disk shape, sometimes called the discocyte. This biconcavity is most pronounced in the dog. Species in which the discocyte is not the norm include goats (flat, irregularly shaped RBCs) camelids (oval RBCs), and some cervids (sickle-shaped RBCs). One of the key properties of erythrocytes is deformability; they change shape as they move through the microvasculature. This deformability is a function of interactions between the cell membrane, the cytoskeleton, and intracellular contents. Mature mammalian erythrocytes lack nuclei and organelles, and are thus incapable of transcription, translation, and oxidative metabolism. However, they do require energy for various functions—including maintenance of shape and deformability, active transport, and prevention of oxidative damage—and they generate this energy entirely through glycolysis (also known as the Embden-Meyerhof pathway). In addition to generating adenosine triphosphate (ATP), glycolysis generates nicotinamide adenine dinucleotide (NADH), a reducing agent in the pathway that converts the oxidized, nonfunctional form of hemoglobin, known as methemoglobin, back to its active reduced state. Another antioxidant erythrocyte metabolic pathway, the pentose shunt or hexose monophosphate shunt pathway, generates nicotinamide adenine dinucleotide plus hydrogen (NADPH) to maintain glutathione in the reduced state.

747

748

The concentration of circulating erythrocytes typically decreases postnatally and remains below normal adult levels during the period of rapid body growth. The age at which erythrocyte numbers begin to increase, and the age at which adult levels are reached, varies among species. In dogs, adult values are usually reached between 4 and 6 months of age; in horses, this occurs at approximately 1 year of age. In most species, erythrocytes are larger at birth, and their mean volume decreases as fetal erythrocytes are replaced.

### 13.1.1.1.3.4

#### Granulopoiesis and monocytopoiesis (myelopoiesis)

Granulocytes (neutrophils, eosinophils, basophils) and monocytes have key immunologic functions, including phagocytosis and microbicidal activity (neutrophils and monocyte-derived macrophages); parasitocidal activity and participation in allergic reactions (eosinophils and basophils); antigen processing and presentation; and cytokine production (macrophages). Many molecules influence production of these cell types, including cytokines such as granulocyte and granulocyte-monocyte colony-stimulating factors (G-CSF and GM-CSF, respectively) and interleukins (such as IL-3 and IL-6). Inflammatory mediators stimulate production of cytokines promoting granulopoiesis and monocytopoiesis.

Granulocytic and monocytic cells are sometimes referred to collectively as myeloid cells. (Note: This terminology can be confusing because “myeloid” also has other meanings. In the most general sense, it means having to do with the bone marrow. In the context of hematology, “myeloid” is also sometimes used to mean any hematopoietic cell of a nonlymphoid origin, a distinction reiterated in the classification of leukemias as discussed later in the chapter. In neuroanatomy, the prefixes “myelo-” or “myel-” can refer to the spinal cord or myelin.) The earliest granulocytic or monocytic precursor identifiable by routine light microscopy is the myeloblast, which undergoes maturational division to produce 16 to 32 progeny cells. The normal transit time from myeloblast to mature neutrophil is approximately 5 days. In addition, a reserve of neutrophils is maintained in the bone marrow. The size of this so-called storage pool is species-dependent. (Species differences and clinical significance of the

## Pathologic Basis of Veterinary Disease, 4th Edition

storage pool are discussed in more detail in the section on mechanisms of disease.) The concentration of granulocytes measured in the blood depends on the rate of production and release from the bone marrow, the proportions of cells circulating freely within the vasculature versus those transiently attached to the endothelial surface (marginated), and the rate of migration from the vasculature into tissues. Neutrophils normally are the predominant leukocyte type in blood of most domestic species. Ruminants usually have higher numbers of lymphocytes than neutrophils. Neutrophils are only in circulation for a short time (less than 12 hours).

13.1.1.1.3.5

### Thrombopoiesis

*Thrombopoiesis*—from *thrombos* (Gr., clot)—refers to the production of platelets, which have a central role in primary hemostasis and also participate in coagulation and inflammatory pathways.

Thrombopoietin (Tpo), synthesized primarily in the liver, is the dominant regulator of thrombopoiesis. Unlike Epo, which is up-regulated in response to hypoxia, Tpo is produced at a relatively constant rate (constitutively). The mechanism regulating production is therefore different. Platelets express the Tpo receptor, which binds Tpo in the plasma. When the platelet mass is decreased, less Tpo is bound to platelet receptors, and the increased concentration of Tpo free in the plasma stimulates thrombopoiesis.

Thrombopoiesis differs fundamentally from other forms of hematopoiesis. Platelets (sometimes called thrombocytes) are anucleate cells formed not by maturational division but by shedding of membrane-bound cytoplasmic fragments from precursor cells called megakaryocytes. (Side note: Birds and reptiles produce thrombocytes in the manner of other blood cells and their thrombocytes, and their erythrocytes, are nucleated.) As the name suggests, megakaryocytes are very large cells, much larger than any other hematopoietic cells (Fig. 13-6). Megakaryocytes arise from a progenitor cell and undergo endomitosis to become polyploid (usually 8N-32N). As they mature, megakaryocytes increase in size and their cytoplasm becomes more abundant. They change in staining pattern (Wright's stain of aspirates) from intensely basophilic to eosinophilic, and their nuclei change from round to highly lobulated. Megakaryocytes extend cytoplasmic processes into the lumina of the bone marrow venous sinusoids, where they shed platelets into circulation. The life span of a platelet in circulation is approximately 6 days in the dog.

748

749

13.1.1.1.3.6

### Lymphopoiesis

*Lymphopoiesis* refers to the production of new lymphocytes. T lymphocytes and B lymphocytes are the key effectors of cell-mediated and humoral immunity, respectively. Lymphopoiesis is discussed in more detail in [Chapter 5](#), but a brief overview will be provided here. T lymphocytes originate in the bone marrow and migrate to the thymus, where they undergo differentiation, selection, and maturation processes before migrating to the peripheral lymphoid tissue as effector cells. B-lymphocyte development occurs in two phases, first in an antigen-independent phase in the bone marrow and ileal Peyer's patches (the site of B-lymphocyte development in ruminants), then in an antigen-dependent phase in peripheral lymphoid tissues (such as spleen, lymph nodes, and mucosal associated lymphoid tissue [MALT]). Trafficking of lymphocytes occurs under the direction of chemokine (chemoattractant cytokine) signals. Once they have migrated to the peripheral lymphoid tissue, lymphocytes may undergo clonal expansion in response to antigenic stimulation. Unlike other hematopoietic cells, which circulate only in the blood vessels, lymphocytes travel in both blood and lymphatic vessels, continually recirculating between the two systems. In most species, the majority of lymphocytes in blood circulation are T lymphocytes. Lymphocytes normally are the predominant leukocyte type in blood of ruminants.

13.1.1.2

### COAGULATION AND PLATELET FUNCTION

Hemostasis—from *haima* (Gr., blood) and *stasis* (Gr., “a standing still”)—refers to the cessation of bleeding. The main components responsible for hemostasis are platelets, blood vessels, and the coagulation system. Bleeding disorders may result if any of these systems are perturbed. Although coagulation factors are mainly synthesized in the liver, they are included in this chapter because of their inextricable link with the hematopoietic system.

Physiologic hemostasis involves coordinated processes: formation of a platelet plug at the site of vascular damage (primary hemostasis), development of a cross-linked network of insoluble fibrin that provides further clot stability (secondary hemostasis) and retraction and enzymatic degradation of the clot (tertiary hemostasis). The main components of these processes are summarized in [Figs. 2-14](#) through [2-19](#). Signalment, history, and clinical signs are important in evaluating any patient with a suspected bleeding tendency, but laboratory testing is required to definitively identify specific defects in hemostasis. Routine assays for assessing hemostasis are summarized in [Appendix 13-1](#).

13.1.1.2.1

### Blood Vessels

Blood vessels have numerous functions in hemostasis. Endothelial cells produce and metabolize many molecules involved in promoting and regulating hemostasis (see [Fig. 2-17](#)). For example, they produce prothrombotic molecules, such as von Willebrand factor (vWF) and thromboxane A<sub>2</sub>; antithrombotic molecules, such as prostacyclin (PGI<sub>2</sub>), thrombomodulin, and nitric oxide; and fibrinolytic molecules, such as tissue plasminogen activator. When a blood vessel is damaged, a rapid, transient neuromechanical vasoconstriction occurs in response. Collagen underlying the damaged endothelium provides structural support for platelet adhesion and clot formation, and also acts as a key biochemical activator of platelets and the intrinsic pathway of the coagulation system (see next section).

13.1.1.2.2

### Coagulation System

Stopping hemorrhage from a damaged blood vessel ultimately depends on the formation of a stable fibrin clot. This process depends on a number of plasma proteins, or clotting factors, that normally circulate in an inactive proenzyme state. These clotting factors, together with other molecules, including nonenzymatic proteins, calcium, and platelet phospholipids, are known collectively as the coagulation system. Activation of the coagulation system initiates a series of linked enzymatic reactions that result in the production of thrombin. Thrombin converts the soluble plasma protein fibrinogen to fibrin, which in turn is enzymatically cross-linked to form an insoluble clot. The coagulation system is conventionally considered to consist of three interrelated pathways for ease of understanding and interpretation of test results. These pathways—the intrinsic, extrinsic, and common pathways—are summarized in [Fig. 2-15](#).

749

750

Anticoagulant and fibrinolytic pathways provide critical “checks and balances.” These pathways are initiated simultaneously with activation of the coagulation system. Procoagulant and anticoagulant pathways are regulated at multiple levels, and normally maintained in a balance that avoids hypercoagulable or hypocoagulable states. Some key regulators of hemostasis are listed in [Box 13-1](#). Counter-regulatory mechanisms are critical to the prevention of inappropriate or excessive clotting, and to the eventual dissolution of the clot (fibrinolysis) after it has formed. Fibrinolysis results from the action of plasmin on fibrin (see [Figs. 2-15](#) and [2-16](#)). The inactive proenzyme plasminogen is converted to plasmin by several molecules, including tissue plasminogen activator, factor XII, and thrombin. Note that some of these molecules (e.g., factor XII and thrombin) have both procoagulant and anticoagulant effects. There are also regulators of fibrinolysis, including inhibitors of plasminogen and plasmin. Fibrinolysis results in production of fibrin degradation products (FDPs). D-dimer is a specific type of FDP that results from the degradation of insoluble cross-linked fibrin. Fibrinolytic products (FDPs and D-dimer) in the blood are often measured to detect inappropriate coagulation and are also of clinical importance because they can impair hemostasis by inhibiting fibrin polymerization and platelet function.

13.1.1.2.2.1

#### Box 13-1 Key Regulators of Hemostasis

- Antithrombin (AT; formerly known as antithrombin III, ATIII)—inactivates thrombin; heparin potentiates activity of AT
- Protein C (with its cofactor, Protein S)—inactivates factors Va and VIIIa
- Thrombin—in addition to its procoagulant and platelet-activating activities, thrombin also: converts plasminogen to plasmin, which lyses fibrin; activates Protein C; and stimulates production of prostacyclin (PGI<sub>2</sub>), a platelet inhibitor and vasodilator
- Thrombomodulin—binds thrombin, promotes thrombin–Protein C interactions

13.1.1.2.2.2

### Platelets

Platelets normally circulate in a quiescent state, as flattened disks. Activation of platelets is triggered by soluble agonists, such as thrombin, or insoluble agonists, such as collagen. Platelets express surface receptors for fibrinogen, vWF, collagen, and other ligands. Other key features of platelets include a network of membrane invaginations known as the open canalicular system (not present in cattle), which facilitates the expansion of surface area and release of granule contents in response to activation;

## Pathologic Basis of Veterinary Disease, 4th Edition

---

specialized endoplasmic reticulum known as the dense tubular system that acts as a reservoir for calcium; and cytoskeletal components involved in mediating shape change, release of granule contents, receptor interactions, and clot retraction. When activated, platelets change to more spherical forms with pseudopodia, and participate in a number of related processes at sites of vascular damage:

- Adhesion to exposed subendothelial collagen
- Secretion of bioactive granule contents (including calcium, adenosine diphosphate [ADP], fibrinogen, vWF, histamine, serotonin, and others)
- Aggregation with other platelets
- Eventual fusion with other platelets (a process known as viscous metamorphosis) to form a unified platelet plug

Phospholipids (e.g., phosphatidylserine) expressed on the surface of activated platelets also help to localize the clot to sites of vascular damage.

### 13.1.1.3 LYMPHATIC SYSTEM

Under the classification of the *Nomina Anatomica Veterinaria*, the thymus, spleen, lymph nodes, and lymph nodules are part of the lymphatic system. They are also part of the immune system. The thymus is one of the two primary lymphoid organs (the other is the bone marrow), and these are defined as the sites at which the cellular components of the immune system are formed. The spleen, lymph nodes, and lymph nodules are secondary lymphoid organs and thus are responsible for the immune responses (i.e., production of antibody and cell-mediated immunity). However, because the spleen and lymph nodes contain numerous cells of the monocyte-macrophage system, they also have functions outside those of the immune system, such as phagocytosis of nonantigenic materials like carbon, and in the case of the spleen, senescent and altered erythrocytes.

#### 13.1.1.3.1 Thymus

The thymus is classified as a component of the lymphatic system, but has also been called a lymphoepithelial organ because of its epithelial component. The thymus is essential for the development and function of the immune system, specifically for the development of T lymphocytes. Histologically it is divided into two portions, the stromal portion and the thymocytes portion (T lymphocytes at different stages of maturation). Unlike the spleen and lymph node, the stroma of the thymus consists of epithelial cells as well as macrophages and dendritic cells. The stromal portions of the thymus are derived embryologically from branchial pouches and the third pharyngeal cleft. The capsule, trabeculae, and blood vessels arise from the mesoderm of a branchial arch. The lymphoid component originates during gestation from hematopoietic progenitor cells, initially derived from the fetal liver and later from the bone marrow. The epithelial component consists of individual cells in the cortex and medulla and aggregates of epithelial cells in the medulla. The latter are called Hassall's corpuscles, a characteristic histological feature of the thymus. Cortical and medullary epithelial cells contribute to the microenvironment essential for T-lymphocyte development in neonate and adult thymuses. The thymus also contains reticular cells (a meshwork of specialized fibroblast-like cells with long interdigitating filamentous projections), macrophages interspersed among the reticular cells, and occasional myoid (smooth musclelike) cells.

750

751

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The shape and location of the thymus vary among young domestic animals. In ruminants and pigs, the thymus has two lobes: cervical and thoracic. The cervical lobe is large and extends along the sides of the cervical trachea. The size of the cervical lobe varies in cats and horses but is usually small. Dogs do not have a cervical lobe. The thoracic lobe is present in all domestic animals and lies in the cranial mediastinum, ventrally in the horse, pig, and dog and dorsally in ruminants.

The thymus is divided into incomplete lobules each of which has a cortex and a medulla, with the medulla being confluent centrally (Fig. 13-7). On the basis of functional and epithelial components, three zones are recognized: a subcapsular zone, a cortex, and a medulla. Bone marrow–derived T-lymphocytes progenitor cells enter the circulation, travel to the thymus, and enter at the subcapsular zone (Fig. 13-8). Here they begin their maturation into T lymphocytes as they traverse the thymic cortex to the medulla. In the cortex, T lymphocytes that recognize self–major histocompatibility complex (MHC) molecules, but not self-antigens, are permitted to mature by a process called positive selection. Cells that do not recognize MHC molecules are removed by apoptosis. Those T lymphocytes that recognize both MHC molecules and self-antigens are removed by phagocytosis by macrophages at the corticomedullary junction, a process called negative selection. Approximately 95% of developing T lymphocytes are destroyed. The remaining mature T lymphocytes leave the thymus through postcapillary venules in the corticomedullary region and are distributed to periarteriolar lymphoid sheaths in the spleen and cortical areas around germinal centers (paracortex) in lymph nodes. The critical balance between production and distribution of T lymphocytes is extremely important in immune homeostasis, so much so that immunodeficiency or autoimmunity may result from inadequate or overzealous activity of a particular subset.

The thymus attains its maximal mass relative to body weight at birth and involutes following sexual maturity; the lymphoid and epithelial components are gradually replaced by loose connective tissue and fat. T lymphocytes continually circulate through splenic and lymph node T-lymphocyte zones, arriving in the blood and departing in the lymph. Expansion of the antigen-specific T lymphocytes occurs subsequent to antigen presentation.

### 13.1.1.3.2

#### Spleen

The functions of the spleen are analogous to those of the lymph nodes. The spleen filters blood of foreign material and microorganisms and removes senescent and altered erythrocytes. It is the largest secondary lymphoid organ (a site at which immune responses occur). An additional function of the spleen in domestic species is to act as a reservoir for blood (reserve pool).

Thus the spleen has components of three anatomic systems—the monocyte-macrophage system, the lymphopoietic system, and the vasculature—and has the following functions:

- Red pulp
  - Removal of foreign material, particularly microorganisms and also senescent and altered erythrocytes (e.g., parasitized, immunocomplexed, or damaged by oxidative processes)
  - Storage of mature erythrocytes in the red pulp vascular spaces
  - Hematopoiesis under certain circumstances
- White pulp

## Pathologic Basis of Veterinary Disease, 4th Edition

- Immunologic response with the production of B lymphocytes and plasma cells to produce antibody and memory lymphocytes

The spleen, suspended in the gastrosplenic ligament and covered by peritoneum, is located in the left cranial hypogastric region of the abdominal cavity between the diaphragm, stomach, and the body wall, except in domestic ruminants, where it is closely adhered to the left dorsolateral aspect of the rumen. The gross morphology (shape and size) of the spleen varies markedly among domestic animals, but in general it is a flattened, elongated organ.

The spleen is covered by a thick fibromuscular capsule from which numerous intertwining fibromuscular trabeculae extend into the parenchyma, forming the supporting stroma for the parenchymal components.

751

The splenic parenchyma, unlike that of many organs, does not have a cortex and medulla but is divided into two distinct structural and functional components: the red pulp and white pulp.

752

**Fig. 13-7 Schematic illustration of the organization of the thymus.** The thymus consists of several incomplete lobules. Each lobule contains an independent outer cortical region, but the central medullary region is shared by adjacent lobules. Trabeculae, extensions of the capsule down to the corticomedullary region, form the boundary of each lobule. The cortex consists of stromal cells and developing T lymphocytes (thymocytes), macrophages, and cortical epithelial cells. Major histocompatibility complex class I and II molecules are present on the surface of the cortical epithelial cells. The characteristic deep blue nucleus staining of the cortex in histological preparation reflects the predominant population of T lymphocytes as compared with the less basophilic medulla, which contains a lower number of thymocytes. Hassall's corpuscles are a characteristic component of the medulla. Hassall's corpuscles are not seen in the cortex. (From Kierszenbaum AL: Histology and cell biology: an introduction to pathology, St Louis, 2002, Mosby.)

## Pathologic Basis of Veterinary Disease, 4th Edition

The artery supplying the spleen is the splenic artery, a branch of the celiac artery, which is a major branch of the abdominal aorta. The splenic artery penetrates the splenic capsule at the hilus, branches, and enters the fibromuscular trabeculae (Fig. 13-9). As these arteries leave the trabeculae, they become central arterioles of the white pulp, and each is surrounded by a cuff of lymphoid cells which forms the periarteriolar lymphoid sheath (PALS). After emerging from the PALS, the arteriole becomes the penicillar arteriole and in the horse, ox, pigs, and cat, its terminal branches empty into the reticular cell lined meshwork of the splenic cords. These spaces in the meshwork are referred to as red pulp vascular spaces or sometimes incorrectly, because they have no endothelium, as capillary beds. In dogs and human beings, branches of the central arteriole of the white pulp enter into venous sinusoids lined by discontinuous endothelium. These anatomic arrangements of opening into sinusoids or red pulp vascular spaces are known as closed and open systems, respectively.

The dog has both open and closed splenic circulations. In either case, the blood is exposed to macrophages and eventually empties into the splenic venules, then into the splenic veins, and ultimately into the portal vein, which drains the abdominal viscera and empties into the liver. Thus the vascular components of the red pulp vary among species depending on whether venous sinusoids are present or not. Understanding the blood flow through the spleen is helpful in understanding how blood comes in contact with the cells of the immune system (white pulp) to facilitate an immunologic response, and cells of the monocyte-macrophage system (red pulp) to enable phagocytosis of foreign materials.

752

753

**Fig. 13-8 Schematic illustration of the histology of the thymus.** The functional thymus consists of two cell populations; the stromal cells and the thymocytes. The stromal cells include (1) the subcapsular epithelial cells also lining the trabeculae and perivascular spaces; (2) the cortical epithelial cells of ectodermal origin; (3) the medullary epithelial cells of endodermal origin that give rise to Hassall's corpuscles; (4) macrophages present in both cortex and medulla, involved in the removal of apoptotic thymocytes eliminated during clonal selection; and (5) dendritic cells of bone marrow origin, confined to the medulla. *TCR*, T-cell receptor. (From Kierszenbaum AL: Histology and cell biology: an introduction to pathology, *St Louis, 2002, Mosby*.)

## Pathologic Basis of Veterinary Disease, 4th Edition

The terminology used to characterize the type of splenic red pulp is confusing. The terms splenic sinuses and splenic sinusoids are both used, but because the endothelium is discontinuous, sinusoid is the correct term. Additionally, confusion arises when the spleen is incorrectly referred to as either sinusal or nonsinusal rather than correctly as sinusoidal or nonsinusoidal.

13.1.1.3.2.1

### Splenic parenchyma

13.1.1.3.2.1.1

#### Red pulp.

This large sievelike vascular reservoir is formed by an interconnected network of splenic sinusoids and red pulp spaces in the dog and human being, which have a sinusoidal spleen. The spleens of the horse, ox, pigs, and cat lack sinusoids and are termed nonsinusoidal. Sinusoids are lined by elongated endothelial cells and are surrounded by macrophages whose cytoplasm may project through slits in the sinusoidal wall into the lumens of the sinusoids to facilitate phagocytosis. Splenic macrophages are responsible for the phagocytosis of blood-borne foreign material, senescent erythrocytes and damaged cells, such as in immune-mediated cytopenias. In nonsinusoidal spleens, the macrophages of the splenic cords of the red pulp perform these functions.

**Fig. 13-9 Schematic representation of the human spleen.** The blood flow depicted is applicable in domestic animals only to the canine spleen, which has splenic sinusoids. The other domestic animals do not have splenic sinusoids. (From Kierszenbaum AL: Histology and cell biology: an introduction to pathology, St Louis, 2002, Mosby.)

The sinusoidal and splenic cord macrophages are part of the monocyte-macrophage system (MMS). MMS cells are of bone marrow origin and include blood monocytes and monocytes that have migrated and differentiated into fixed macrophages in connective tissue throughout the body and within vascular beds of specific organs, such as the spleen (sinusoidal and splenic cord macrophages), lymph nodes (sinus histiocytes), liver (Kupffer cells), lung (pulmonary intravascular macrophages and alveolar macrophages), and brain (resident and perivascular microglial cells).

In the dog and human beings (species with sinusoidal spleens), macrophages can remove entire erythrocytes (erythrophagocytosis), portions of an erythrocyte's membrane and inclusions in erythrocytes, such as nuclear remnants, Heinz bodies, or rickettsial organisms. The process is called "pitting" in the case of nuclear debris and Heinz bodies. Indeed, the presence of large numbers of nuclear remnants in erythrocytes in blood smears may indicate splenic malfunction. The process of removal of senescent erythrocytes normally does not alter the size of the spleen, but when the spleen has to remove large numbers of defective erythrocytes, as in an acute hemolytic anemia, it is markedly enlarged.

### 13.1.1.3.2.1.1.1

#### Vasculature, storage, and defense spleens.

Spleens have been classified as either storage or defense spleens. Human spleens have little storage capacity for blood and are classified as defense spleens. The spleens of domestic animals have both storage and defense functions and are classified as storage spleens. They have trabeculae and capsules with a high percentage of smooth muscle, which allows them to expand and contract. These are features of the equine, canine, and feline spleens, which have considerable capacity. It has been claimed that the canine spleen can store one third of the dog's erythrocytes while the animal sleeps. In contrast, spleens whose capsules and trabeculae have a low percentage of smooth muscle and elastic fibers, and thus cannot expand and contract (rabbit and human being), are designated as defense spleens. The spleens of ruminants and the pig are intermediate in the amount of smooth muscle. Storage spleens expand and contract quickly under the influence of the autonomic nervous system (sympathetic and vagal fibers; catecholamines, "flight or fight") and other circulatory perturbations, such as in hypovolemic and/or cardiogenic shock (see sections on small spleens and splenic contraction).

### 13.1.1.3.2.1.1.2

#### Hematopoiesis.

Although hematopoiesis takes place in part in the spleen of the fetus, this ceases shortly after birth in most species. However, often but not necessarily under conditions of severe demand, for example in a severe and prolonged anemia, hematopoiesis can resume. This is called extramedullary hematopoiesis (EMH).

EMH is also present as an incidental finding in splenic nodular hyperplasia (see Splenic Nodules with Firm Consistency). Also, B lymphocytes in the germinal centers of splenic follicles are activated to proliferate and differentiate into antibody producing plasma cells, a form of lymphopoiesis. The marginal zone is the region between red and white pulp, the zone around the PALS and the splenic follicles. It is supplied by a branch of the central arteriole of the white pulp (Fig. 13-9) from which lymphocytes enter the spleen, and blood-borne antigens are taken up by dendritic cells and transported to the PALS for presentation to T lymphocytes. Other secondary lymphoid tissue, such as lymph nodes, do not have a marginal zone.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

13.1.1.3.2.1.2

### White pulp.

The adaptive immune system component of the spleen consists of distinct organized foci of lymphoid tissue. These are the periarteriolar lymphoid sheaths (PALS, which are T-lymphocyte areas), which surround a so-called central artery of the white pulp, and splenic follicles (B-lymphocyte areas), which lie at the periphery of the PALS.

Normal foci of white pulp are so small that they are not usually visible on gross examination of a cut tissue section. However, if they are enlarged either by lymphoid hyperplasia as a result of a response to an antigenic stimulus or by a neoplastic process (e.g., lymphoma), these foci initially are evident on the cut surface as 0.5- to 1.0-mm white dots scattered through the red pulp. Also in animals with storage spleens (see previous discussion), the distention of the red pulp by blood may obscure white pulp that is enlarged.

The two primary functions of the splenic white pulp are trapping and phagocytosis of blood-borne foreign antigens and the presentation of antigens to T lymphocytes, which result in activation of T and B lymphocytes and the production of antibodies. Antibodies leave the spleen through the efferent lymphatics, which exit the spleen at the hilus, and then depending on the species, connect to the splenic, caudal mediastinal, or celiac lymph nodes. They then travel to the thoracic duct, which empties into the systemic circulation at the origin of the cranial vena cava or into one of its adjacent tributaries. Plasma cells after their formation in the germinal centers of the splenic follicles enter the red pulp and secrete antibody.

13.1.1.3.3

### Lymph Nodes

Lymph nodes, along with the spleen and mucosal-associated lymphoid tissue (MALT), which includes tonsils, BALT (bronchus-associated lymphoid tissue), and GALT (gut-associated lymphoid tissue), are classified as secondary lymphoid organs—defined as the site of production of antibody and cells for cell-mediated immunity.

755

A lymph node includes components of two different anatomic systems, the monocyte-macrophage system and the hematopoietic (lymphopoietic) system. Its most important functions are filtration of lymph and immune responses.

756

The lymph node is enclosed almost completely by a fibrous capsule that is pierced by multiple afferent lymphatics, which empty into the subcapsular sinus. Efferent lymphatics exit and blood vessels enter and exit at the hilus.

In a cross section of lymph nodes, there are two main areas: cortex (outer) and a medulla (inner) (Fig. 13-10). The outer cortex contains the lymphoid follicles. The morphological and functional organization of the lymphoid follicle is identical to that of the splenic lymphoid follicle, except that the marginal zone is absent in the lymph node. Lymphoid follicles are almost absent from the lymph nodes of germ-free and unstimulated neonatal animals. Once lymph nodes are antigenically stimulated, lymphoid follicles form. These initially have no germinal centers and are termed primary lymphoid follicles. With continued antigenic stimulation, germinal centers—the site of proliferating B lymphocytes—develop, and these lymphoid follicles are designated secondary lymphoid follicles. The inner cortex (paracortex) consists of diffuse lymphoid tissue containing T lymphocytes and high endothelial venules (HEVs). T lymphocytes arrive in the blood and then migrate into the lymph node via the HEV.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Also in the cortex are trabeculae, which are collagenous bands extending radially inward from the capsule. They are often surrounded by trabecular (also called paratrabecular) sinuses, which are continuous with the subcapsular sinus and empty into the medullary sinuses (Fig. 13-10).

The medulla consists of two components: (1) medullary cords containing macrophages and lymphocytes—and in an immunologically stimulated lymph node, plasma cells actively secreting antibody; and (2) medullary sinuses surrounded by macrophages, which actively phagocytose foreign material and bacteria.

The porcine lymph node has a different structure. There is one afferent lymphatic that enters at the hilus and discharges lymph into the center of the node, from where it flows to the subcapsular sinus and then drains into several efferent lymphatics, which pierce the capsule.

All lymph nodes receive afferent lymphatic vessels from specific areas of the body. For example, peripheral lymph nodes, such as the popliteal and superficial inguinal, drain the hind leg. Central lymph nodes, such as the tracheobronchial and mesenteric lymph nodes (lymphocenters), drain the lungs and gastrointestinal tract, respectively. The term *lymphocenter* is used in veterinary anatomy for a lymph node or a group of lymph nodes that occur constantly in the same region and receive lymphatic vessels from the same region in all species.

### 13.1.1.3.4

#### Lymphoid Nodules

This category includes so-called solitary and aggregated lymphoid nodules. Lymphoid nodules are present in the mucosal-associated lymphoid tissue (MALT), which includes the BALT (bronchus-associated lymphoid tissue), GALT (gut-associated lymphoid tissue), and lymphoid nodules at other sites, such as the tonsils and mucosa of the nasal cavity, conjunctiva, and urinary bladder. These lymphoid nodules consist of lymph follicles and some loose lymphoid tissue. The follicles, if antigenically stimulated can have active germinal centers. Peyer's patches in the small intestine and aggregated lymphoid nodules in the cecum and colon lie in the mucosa and are overlaid by a special epithelium known as the follicle-associated epithelium (FAE) in which there are numerous M cells. These M cells deliver macromolecules (including antigens), particles, pathogenic bacteria, and viruses across the epithelium to an area rich in dendritic cells, which are able to transport the material into the Peyer's patches. Live attenuated salmonella induce dendritic cells in the subepithelial tissue to migrate to the lymph follicle (B-lymphocyte) and parafollicular (T-lymphocyte) areas of Peyer's patches. Other pathogenic bacteria known or believed to enter via the M cells include *Listeria monocytogenes*, *Mycobacterium avium* ssp. *paratuberculosis*, and *Yersinia pseudotuberculosis*. The scrapie agent has been demonstrated to enter through M cells and accumulates in Peyer's patches. HIV and poliovirus are also believed to use this route.

### 13.1.1.3.5

#### Hemal Nodes

Although these are often considered to be unique to ruminants, they have also been found in horses and primates. Their architecture resembles that of a lymph node with lymph follicles and sinuses, except that the latter are filled with blood (Fig. 13-11). Some authors regard them as “miniature spleens.” It was once thought that they had no afferent or efferent lymphatics, but these have been identified. As erythrophagocytosis can be present, it is presumed that hemal nodes can filter blood and remove senescent erythrocytes.

### 13.1.2.1.2

#### Abnormal Proliferation

The classic nomenclature for describing different types of abnormal cellular proliferations applies to the hematopoietic system, with some exceptions and modifications. Hyperplasia, an increase in cell number, may be an obviously appropriate response to a stimulus (e.g., erythroid hyperplasia in response to hypoxemia, or lymphoid hyperplasia in response to antigenic stimulation). In other situations, hyperplasia is a secondary phenomenon for which the specific stimulus is not clear—for example, a number of conditions (inflammation, neoplasia, iron deficiency, asplenia, and others) are associated with reactive thrombocytosis, in which an increased concentration of circulating platelets reflects megakaryocytic hyperplasia. Sometimes hyperplasia is idiopathic. For example, splenic nodular hyperplasia, which often includes a hematopoietic component, is frequently an incidental finding.

Hypertrophy, an increase in cell size, is not a conventional description for hematopoietic cells or for bone marrow as an organ. Abnormally large hematopoietic cells are considered evidence of dysplasia, or altered cell formation (alterations to shape or organization of cells are also evidence of dysplasia). Dysplasia of hematopoietic cells, indicating dyshematopoiesis, may be primary (idiopathic) or secondary to a number of conditions, including infection, nutritional imbalance, and toxicosis. Unfortunately the terminology is sometimes confusing. For example, myelodysplastic syndromes are clonal hematopoietic stem cell disorders that are, in fact, neoplastic (see the later section titled Hematopoietic Neoplasia). Splenic hypertrophy is usually referred to as splenomegaly and may reflect processes other than hyperplasia or cellular hypertrophy. Similarly, lymph node enlargement is typically referred to as lymphadenopathy or lymphadenomegaly and may reflect lymphoid hyperplasia or other processes (e.g., neoplasia, inflammation, or edema).

Replacement of hematopoietic tissue in the bone marrow by abnormal tissue, usually fibrous tissue or malignant cells, is known as myelophthisis. The term *metaplasia*, describing the replacement of cells normally comprising a tissue with another well-differentiated cell type, is rarely used to describe hematopoietic tissues in veterinary medicine, although in human beings, the terms myeloid metaplasia and extramedullary hematopoiesis are sometimes used interchangeably. Similarly, the term *atrophy*—meaning a diminution in the size of a cell, tissue, organ, or part—is seldom used to describe bone marrow. Instead a decrease in bone marrow hematopoietic tissue is typically referred to as hypoplasia, as discussed later in the section on cytopenias. The absence of bone marrow hematopoietic tissue of a particular lineage is typically referred to as aplasia or, if affecting all lineages, by the misleading term *aplastic anemia*. An exception is a condition sometimes called “serous atrophy of fat,” a condition associated with cachexia or

## Pathologic Basis of Veterinary Disease, 4th Edition

---

starvation in which fat is catabolized and bone marrow reticular cells produce a mucoid ground substance. However, neither hematopoietic cells nor fat is necessarily absent from the bone marrow in this condition, and other names, such as “gelatinous transformation,” have been suggested to describe it.

Neoplasia of bone marrow or lymphoid organs may be primary or due to metastasis (secondary). 758

Hematopoietic neoplasia may arise from any hematopoietic lineage. Leukemias are neoplasms arising from bone marrow hematopoietic cells, and are conventionally classified according to two criteria: as lymphocytic (lymphoid) or myelogenous (myeloid), based on the cell of origin; and as acute or chronic, based on the degree of differentiation of the neoplastic cells and on their biologic behavior. Myeloid leukemias encompass the range of leukemias of nonlymphoid origin. Chronic leukemias are characterized by well-differentiated cells and slowly progressive disease. Conversely, acute leukemias are characterized by poorly differentiated cells and an aggressive clinical course. This classification system is simplistic but facilitates communication and is useful for general understanding. Within each of the categories are subclassifications that may have different prognoses. Hematopoietic neoplasia may also originate from outside the bone marrow. For example, *lymphoma* (also known as malignant lymphoma or lymphosarcoma) refers to a group of malignant lymphoid neoplasms arising from lymphoid organs or tissues other than the bone marrow. Specific types of hematopoietic neoplasia (leukemias, lymphomas, and others) are covered later in this chapter. 759

### 13.1.2.1.3 Abnormal Concentrations

#### 13.1.2.1.3.1 Cytopenias

Cytopenia—derived from *kytos* (Gr., hollow vessel) and *penia* (Gr., poverty)—refers to a deficiency of blood cells, hence the terms neutropenia, thrombocytopenia, lymphopenia, and so on. Basic mechanisms causing cytopenias include decreased production (hypoplasia), increased destruction, blood loss, consumption, and altered anatomic distribution (e.g., shifts between marginated and circulating compartments in the blood, or between the spleen and the peripheral blood circulation). Most of these basic mechanisms may cause cytopenias of more than one lineage, and some processes affect multiple lineages simultaneously. Sustained decreased production of all three major bone marrow hematopoietic lineages results in pancytopenia (anemia, neutropenia, and thrombocytopenia). Pancytopenia may occur because of myelophthisis, in which normal bone marrow tissue is replaced by abnormal cells or tissue (as in the case of effacement by malignant cells or fibrous tissue) or because of an abnormality of hematopoietic cells themselves. Destruction of hematopoietic stem cells and progenitor cells causes a condition known as aplastic anemia, or aplastic cytopenia, which is discussed further in the section on specific diseases.

The pattern of development of cytopenias is partly a function of normal blood cell kinetics. Recall that the life span of different blood cells in circulation varies markedly (neutrophils, hours; platelets, days; erythrocytes, months). Thus severe neutropenia typically develops within 1 week after cessation of granulopoiesis, after the bone marrow storage pool of neutrophils is depleted, whereas severe thrombocytopenia typically develops in the second week after cessation of thrombopoiesis. Anemia develops much more slowly after the cessation of erythropoiesis, if at all, depending in part on how rapidly the marrow recovers from the insult and on species variation in the erythrocyte life span.

## Anemia.

*Anemia* refers to subnormal red blood cell mass (i.e., decreased erythrocyte concentration [usually expressed as  $RBC \times 10^6/\mu L$ ], hematocrit [%], or packed cell volume [PCV, %]) or hemoglobin concentration (g/dL). (Note: Hematocrit [Hct] and PCV both express the proportion of blood volume that is occupied by erythrocytes, but the terms are not perfectly synonymous—Hct is a calculated value based on the number and size of RBCs, whereas PCV is a measured value based on centrifugation.) Anemia causes clinical signs referable to decreased oxygen-carrying capacity (pallor of mucous membranes, lethargy, weakness, exercise intolerance) and may also result in detectable abnormalities because of tissue hypoxia (e.g., increased liver enzyme activities as a result of hypoxia-induced damage to hepatocytes). Anemia also causes decreased viscosity of the blood, and in marked cases frequently causes heart murmurs as a result of a decrease in laminar blood flow.

Classifying anemia as regenerative or nonregenerative is clinically useful because it provides information about the mechanism of disease (Table 13-1). The hallmark of regenerative anemias, except in horses, is reticulocytosis (i.e., increased numbers of circulating reticulocytes [immature erythrocytes]), which is evident on examination of a blood smear as polychromasia. In ruminants, reticulocytosis is often accompanied by basophilic stippling (Fig. 13-12).

Reticulocytosis indicates increased bone marrow erythropoiesis and release of erythrocytes before they are fully mature (further back in the production “pipeline”). Reticulocytosis is an appropriate response to anemia. A strong regenerative response may produce an increased mean cell volume (MCV) and decreased mean cell hemoglobin concentration (MCHC) on the complete blood count (CBC), because reticulocytes are larger and have a lower hemoglobin concentration than mature erythrocytes. Horses are an exception to this classification scheme because they do not release reticulocytes into circulation even when their marrow is producing increased numbers of erythrocytes. Horses with a regenerative response may have an increased MCV and red cell distribution width (an index of variation in cell size). But definitive determination of regeneration in a horse requires either bone marrow examination, in which case the evidence of regeneration is erythroid hyperplasia, or sequential CBCs, in which case the evidence of regeneration is an increase in red cell mass over time. Punctate reticulocytes in cats are evident when blood is stained with new methylene blue, but they are not counted as reticulocytes on the CBC, and they have the same appearance as mature erythrocytes on routine blood smear examination.

759

760

Table 13-1 Classification of Anemia

	Regenerative	Nonregenerative
CBC hallmarks	Reticulocytosis (except horses) Polychromasia, anisocytosis ± ↑ MCV, MCV, ↓ MCHC (iron deficiency) ↓ MCHC	Absence of reticulocytosis ± ↓
CBC, Complete blood count; GI, gastrointestinal; MCHC, mean cell hemoglobin concentration; MCV, mean cell volume; PFK, phosphofructokinase; PK, pyruvate kinase; RBC, red blood cell.		

## Pathologic Basis of Veterinary Disease, 4th Edition

	Hemorrhage	Hemolysis	
Causes	Trauma Hemostasis defect Neoplasia GI ulceration  Parasitism	Extravascular: immune-mediated; hemoparasitism toxicosis; PK, PFK deficiencies  Intravascular: immune-mediated; hemoparasitism; toxicity, enzymatic (e.g., bacterial phospholipases); hypophosphatemia; PFK deficiency (with alkalemia)	Anemia of chronic disease: ↓ iron availability; ↑ RBC turnover Altered humoral signaling: ↓ erythropoietin; endocrinopathies Ineffective erythropoiesis: immune-mediated; feline leukemia virus Primary production problem: toxicity; myelophthisis; pure red cell aplasia; pancytopenic disorders Iron deficiency*
Notes	Evaluate in concert with history, physical exam, other lab data.  Fluid shift occurs within hours of hemorrhage. Regeneration takes approximately 3–4 days to become evident in blood, 7–10 days to reach maximum response.		Evaluate in concert with history, physical exam; other lab data may be indicated. Bone marrow evaluation may be indicated.

\* Iron deficiency anemia is sometimes regenerative.

**Fig. 13-12 Basophilic stippling and polychromasia, bovine blood smear.** Erythrocytes from this cow with regenerative anemia include several cells with basophilic stippling (*arrow*) and two polychromatophilic cells (reticulocytes) (*arrowheads*). Wright's stain. (Courtesy Dr. M.M. Fry, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Another finding that may accompany regeneration, in addition to reticulocytosis, is the presence of nucleated erythroid cells (nRBCs). However, the presence of circulating nRBCs is not in itself definitive evidence of regeneration, and in fact may signify dyserythropoiesis (e.g., because of lead poisoning or bone marrow disease) or splenic dysfunction. When nRBCs are present as part of a regenerative response to anemia, they should be in low numbers relative to the numbers of reticulocytes.

Recall that the stimulus for increased erythropoiesis is increased secretion of Epo in response to hypoxemia. Although the action of Epo on erythropoiesis is rapid, evidence of a regenerative response is not immediately apparent in a blood sample. One of the main effects of Epo is to expand the pool of early stage erythroid precursors, and it takes time for these cells to differentiate to the point where they are released into circulation. In a case of acute blood loss, for example, it typically takes 3 to 4 days until reticulocytosis is evident on the CBC, and several more days until the regenerative response peaks. A similar lag occurs in cases of acute hemolysis. The term “preregenerative” is sometimes used to describe anemia with a regenerative response that is impending but not yet apparent on the CBC. Confirming a regenerative response in such cases requires either evidence of erythroid hyperplasia in the bone marrow or emergence of a reticulocytosis on subsequent days.

Regenerative anemia occurs because of hemorrhage or hemolysis. Some find it useful to remember these as the “2 Hs” or, alternatively, the “2 Ls” (loss or lysis). In the case of hemorrhage, erythrocytes and the other components of blood escape from the vasculature. Hemorrhage may be acute or chronic, internal or external. Causes of hemorrhage include trauma, abnormal hemostasis, certain forms of parasitism, ulceration, and neoplasia. In general, regenerative anemias do not occur because of a problem with erythropoiesis but one that occurs after erythrocytes are made. However, it is important to note that chronic hemorrhage can deplete the body's iron stores, leading to iron-deficiency anemia, which may be either regenerative or nonregenerative. A regenerative response may occur when the deficiency is resolving or temporarily compensated (e.g., when hemorrhage ceases, or when a patient suddenly gains access to increased dietary or parenteral iron). Nonregenerative anemias, and iron-deficiency anemia specifically, are discussed in more detail later in this chapter.

Hemolysis may be intravascular—in which case erythrocytes release their contents, mostly hemoglobin, directly into the blood—or extravascular, in which case macrophages phagocytose erythrocytes, and little or no hemoglobin is released into the blood. Both forms (mostly extravascular hemolysis) occur as part of normal homeostasis and involve pathways to conserve iron and other reusable components in hematopoiesis. However, some diseases are associated with increased destruction of erythrocytes by one, or both, of these mechanisms. The next sections discuss basic mechanisms of intravascular and extravascular hemolysis in health and disease in more detail.

13.1.2.1.3.1.1.1

### Mechanisms of hemolysis.

Normal turnover of erythrocytes occurs mainly by extravascular hemolysis, in which senescent erythrocytes are phagocytosed by macrophages in the spleen and to a lesser extent in other organs, such as liver (Kupffer cells) and bone marrow. The exact controls are not clear, but factors that likely play a role include the following:

- Exposure of membrane components normally sequestered on the inner leaflet of the cell membrane, particularly phosphatidylserine (this mechanism is also important in apoptosis of other cell types)
- Decreased deformability
- Binding of IgG and/or complement
- Oxidative damage

Macrophages degrade erythrocytes into reusable constituents, such as iron and amino acids, and the waste product bilirubin. Intravascular hemolysis occurs normally at only very low levels. Hemoglobin is a tetramer that, when released from the erythrocyte into the blood, splits into dimers that bind to a plasma protein called haptoglobin. The hemoglobin-haptoglobin complex is taken up by hepatocytes and macrophages. This is the major pathway for handling free hemoglobin. However, free hemoglobin may also oxidize to form methemoglobin, which dissociates to form metheme and globin. Metheme binds to a plasma protein called hemopexin, which is taken up by hepatocytes and macrophages in a similar manner to hemoglobin-haptoglobin complexes. Free heme in the reduced form binds to albumin, from which it is taken up in the liver and converted into bilirubin.

In hemolytic anemia, erythrocytes are destroyed at an increased rate. Whether the mechanism is intravascular or extravascular, or a combination, depends on the specific disease process (specific diseases are discussed later in this chapter). A classic sequela of hemolytic anemias in general is hyperbilirubinemia, an increase in the plasma concentration of bilirubin. Bilirubin is a yellow pigment, which explains why hyperbilirubinemia, if severe enough, causes icterus—the grossly visible yellowing of serum or tissue (Fig. 13-13). Icterus of mucous membranes, skin, and other tissue is known as jaundice. Icterus is usually detectable when the plasma bilirubin concentration exceeds 2 mg/dL. In hemolytic diseases, hyperbilirubinemia is due to prehepatic disease (i.e., increased turnover of erythrocytes, as described earlier), but it is important to note that it can also be due to hepatic or posthepatic (cholestatic) disease.

Laboratory findings and clinical observations may point to a specific mechanism of hemolysis. In patients with extravascular hemolytic anemia, increased destruction of erythrocytes by splenic macrophages often results in splenomegaly (Fig. 13-14). Splenomegaly may also occur because of other conditions, as discussed elsewhere in this chapter. Intravascular hemolysis is grossly evident as hemoglobinemia, pink-tinged plasma or serum, if the concentration of extracellular hemoglobin is greater than approximately 50 mg/dL. Haptoglobin is saturated with dimeric hemoglobin at a concentration of approximately 150 mg/dL. When haptoglobin is saturated, any remaining free hemoglobin is of low enough molecular weight to pass through the renal glomerular filter into the urine (hemoglobinuria), imparting a pink or red discoloration to the urine. Thus extracellular hemoglobin can cause gross discoloration of the plasma, where it is bound to haptoglobin, before becoming grossly visible in urine. The half-life of haptoglobin is markedly decreased when bound to hemoglobin, so when large amounts of haptoglobin-hemoglobin complex are formed, the concentration of haptoglobin in the blood decreases and hemoglobin can pass through the glomerulus at even lower concentrations. Although hemoglobin itself is not nephrotoxic, hemoglobinuria is a contributing factor in the renal tubular necrosis (hemoglobinuric nephrosis) that often occurs in cases of acute intravascular

761

762

## Pathologic Basis of Veterinary Disease, 4th Edition

---

hemolysis (see [Chapter 11](#)). A similar lesion occurs in the kidneys of individuals with marked muscle damage and resulting myoglobinuria.

**Fig. 13-13 Icterus, immune-mediated hemolytic anemia, subcutaneous fat, splenomegaly, spleen, dog.** The marked yellow discoloration of tissues, most strikingly visible in the subcutaneous fat, is from high concentrations of serum bilirubin produced as a result of the hemolytic anemia. (*Courtesy Dr. J.A. Ramos-Vara, College of Veterinary Medicine, Michigan State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.*)

Fig. 13-14 **Splenomegaly, fatal hemolytic anemia, *Mycoplasma suis*, pig.** The spleen is extremely enlarged, meaty, and congested. (Courtesy College of Veterinary Medicine, University of Illinois.)

Hemoglobinuria cannot be distinguished grossly from hematuria (RBCs in the urine) or myoglobinuria, and both hemoglobin and myoglobin cause a positive reaction for “blood protein” on urine test strips. Comparing the colors of the plasma and the urine may be informative. In contrast to hemoglobin, myoglobin causes gross discoloration of the urine before the plasma is discolored. This is because myoglobin is a low molecular weight monomer, freely filtered by the glomerulus, and does not bind plasma proteins to a significant degree. Hematuria can be distinguished from hemoglobinuria on the basis of microscopic examination of urine sediment (RBCs will be detected in cases of hematuria).

CBC data is often useful in illuminating hemolytic mechanisms. Total hemoglobin concentration is conventionally measured by lysing all the erythrocytes and measuring the hemoglobin in solution spectrophotometrically. The value for mean cell hemoglobin (MCH) is calculated based on the total hemoglobin concentration and the concentration of erythrocytes. The value for MCHC is calculated based on the MCH and MCV. Thus although erythrocytes do not actually contain supranormal concentrations of hemoglobin, an excess of extracellular hemoglobin may cause an artifactual increase in the calculated MCH and MCHC. It is important to remember that similar increases may also occur artifactually because of interference with spectrophotometric measurement of hemoglobin, such as occurs with lipemia.

Extravascular hemolysis also often produces characteristic CBC abnormalities that may reflect the mechanism of disease. For example, spherocytosis and autoagglutination are hallmarks of immune-mediated hemolytic anemia. Spherocytes form when macrophages (mainly in the spleen) phagocytose part of an erythrocyte plasma membrane bound with autoantibody (Fig. 13-15). The remaining portion of the RBC assumes a spherical shape, thus preserving maximal volume. This

change in shape results in decreased deformability of the cells. Erythrocytes must be extremely pliable to traverse the splenic red pulp and sinusoidal walls (Fig. 13-16); spherocytes, therefore, tend to be retained in the spleen in close association with macrophages with risk of further injury and eventual destruction. In the dog, spherocytes appear smaller than normal and have uniform staining (Fig. 13-17, A), in contrast to normal RBCs, which have a region of central pallor imparted by their biconcave shape. This difference in staining between spherocytes and normal RBCs is not consistently discernible in many other domestic animals (including cats, horses, and cattle), whose erythrocytes differ from those of the dog in that they are smaller and have less pronounced biconcavity and therefore less pronounced central pallor. Autoagglutination occurs because of cross-linking of antibodies bound to erythrocytes. Autoagglutination is evident microscopically as clusters of erythrocytes, and macroscopically as blood with a grainy consistency (Fig. 13-17, B). Autoagglutination may also result in a falsely increased MCV and decreased RBC concentration when clustered cells are mistakenly counted as single cells by automated hematology analyzers.

762

763

**Fig. 13-15 Schematic representation of the mechanisms of spherocytosis and extravascular hemolysis (EVH).** Hereditary spherocytosis occurs in human beings (as shown here) because of mutations that weaken the connections between cytoskeletal and membrane proteins. In cases of immune-mediated hemolytic anemia, the most frequent cause of spherocytes in animals, the underlying disease mechanism is different—spherocytes form when portions of the erythrocyte membrane bound with autoantibody are phagocytosed by macrophages—but the net result (spherocytosis and EVH) is similar to what is shown here. GP, Glycoprotein. (From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

**Fig. 13-16 Schematic representation of a human splenic sinusoid.**

A red blood cell (RBC) is in the process of squeezing from the red pulp cords into the sinus lumen. Note the degree of deformability required for RBCs to pass through the wall of the sinus. 763

**Fig. 13-17 Immune-mediated hemolytic anemia, canine blood, dog.** **A**, Spherocytosis. Numerous spherocytes (*arrows*) and several polychromatophilic cells, one of which (*arrowhead*) contains a nuclear remnant known as a Howell-Jolly body, are visible. Wright's stain. **B**, Autoagglutination. Note the grossly visible agglutination. **C**, Spherocytosis and agglutination. Note the spherocytes (*arrows*) and microscopic agglutination of erythrocytes in a dog that received a blood transfusion. These abnormalities presumably indicate immune-mediated destruction of the donor erythrocytes. Wright's stain. (**A**, Courtesy Dr. M.M. Fry, College of Veterinary Medicine, University of Tennessee. **B** and **C**, From Harvey JW: *Atlas of veterinary hematology: blood and bone marrow of domestic animals*, Philadelphia, 2001, Saunders.)

Oxidative damage to erythrocytes occurs when normal antioxidative pathways that generate reducing agents (such as glutathione, NADH, and NADPH), are compromised or overwhelmed, and can result in hemolytic anemia, abnormal hemoglobin function, or both. Hemolysis due to oxidative damage may be extravascular or intravascular, or a combination (predominant forms of hemolysis are discussed further in the section on specific diseases). Evidence of oxidative damage to erythrocytes may be apparent on examination of a blood smear, or even on gross physical examination. Heinz bodies are foci of denatured globin that interact with the erythrocyte

## Pathologic Basis of Veterinary Disease, 4th Edition

membrane. They are usually subtly evident on routine Wright's-stained blood smears as pale circular inclusions or blunt, rounded protrusions of the cell margin and are readily discernible on smears stained with new methylene blue (Fig. 13-18). Cats are particularly susceptible to Heinz body formation and may have low numbers of small Heinz bodies normally. There is not unanimity of opinion, but some clinical pathologists believe that the presence of Heinz bodies in up to 10% of all RBCs in cats is within normal limits. This predisposition is believed to reflect unique features of the feline erythrocyte, whose hemoglobin has more sulfhydryl groups (preferential sites for oxidative damage) than do erythrocytes of other species and may also have lower intrinsic reducing capacity. It is also possible that the feline spleen, which is nonsinusoidal, does not have as efficient a "pitting" function as does a sinusoidal spleen, such as that of the dog (splenic structure and function are discussed in more detail earlier in this chapter). Eccentrocytes, evident as erythrocytes in which one side of the cell has increased pallor, are another manifestation of oxidative damage. They form because of cross-linking of membrane proteins, with adhesion of opposing areas of the cell's inner membrane leaflet, and displacement of most of the hemoglobin toward the other side (Fig. 13-19, H). Oxidative insult may also result in conversion of hemoglobin (iron in the  $\text{Fe}^{2+}$  state) to methemoglobin (iron in the  $\text{Fe}^{3+}$  state), which is incapable of binding oxygen. Methemoglobin is produced normally in small amounts, but reduced back to oxyhemoglobin by the enzyme cytochrome-b<sub>5</sub> reductase (also known as methemoglobin reductase). Methemoglobinemia results when methemoglobin is produced in excessive amounts (because of oxidative insult) or when the normal pathways for maintaining hemoglobin in the  $\text{Fe}^{2+}$  state are impaired (as in cytochrome-b<sub>5</sub> reductase deficiency). When present in sufficiently high concentration (approximately 10% of total hemoglobin), methemoglobin imparts a grossly discernible chocolate color to the blood.

764

765

**Fig. 13-18 Heinz bodies, blood smears.** **A**, Feline blood smear. With routine staining, Heinz bodies appear as pale circular intraerythrocytic inclusions that may protrude from the margin of the cell. Wright's stain. **B**, Canine blood smear. Using a supravital stain, Heinz bodies are blue inclusions and easier to see. New methylene blue stain. (**A and B** Courtesy Dr. M.M. Fry, College of Veterinary Medicine, University of Tennessee.)

Nonregenerative anemias are characterized by a lack of reticulocytosis on the CBC; however, reticulocytosis does not occur in horses even in the context of regeneration. Most often this is due

## Pathologic Basis of Veterinary Disease, 4th Edition

---

to decreased production in the marrow (i.e., erythroid hypoplasia). Erythrocytes circulate for a long time (life span is approximately 100 days in dogs, 70 days in cats, 150 days in horses and cattle), so anemias caused by decreased production tend to develop slowly. The most common form of nonregenerative anemia is known as anemia of inflammation or anemia of chronic disease. In this form of anemia, RBCs are decreased in number, but are normal in mean size and hemoglobin concentration (so-called normocytic, normochromic anemia). It has long been known that patients with inflammatory or other chronic disease often become anemic, and that this condition is associated with increased iron stores in the bone marrow. Sequestration of iron may be a bacteriostatic evolutionary adaptation because many bacteria require iron as a cofactor for growth. In recent years, investigators have begun to elucidate the molecular mechanisms underlying anemia of inflammation. Hepcidin, an acute phase protein synthesized in the liver that was first identified as an antimicrobial peptide, is a key mediator that acts by limiting iron availability. Hepcidin expression increases with inflammation, infection, or iron overload, and decreases with anemia or hypoxia. Anemia of inflammation almost certainly involves factors besides decreased iron availability. For example, experimentally induced sterile inflammation in cats resulted in a shortened erythrocyte life span, suggesting that anemia of inflammation is also a function of increased erythrocyte destruction.

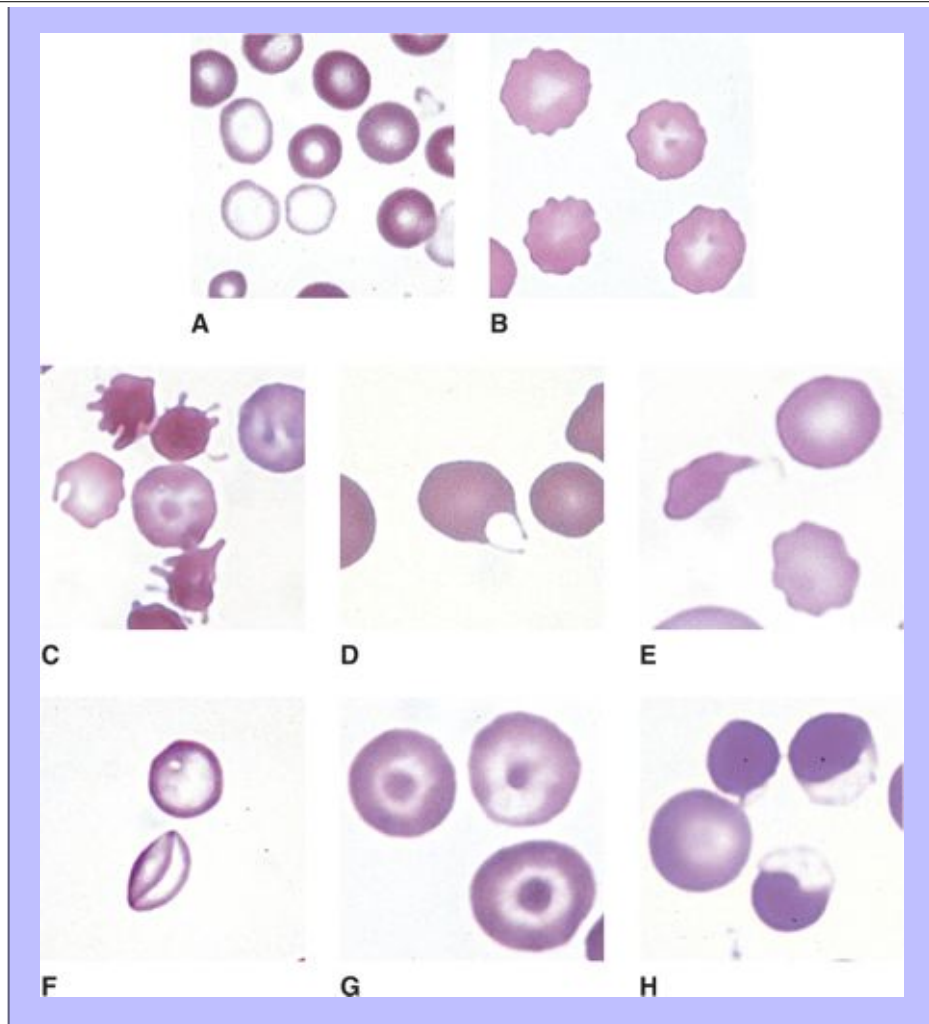

True iron deficiency has long been recognized as a cause of anemia. Iron deficiency occurs most commonly because of chronic blood loss, and thus loss of iron in the form of hemoglobin, and less frequently is due to nutritional deficiency. Although iron deficiency often results in nonregenerative anemia, it is not always so, especially if caused by chronic hemorrhage and when nutritional iron is not a limiting factor. There are many underlying conditions that involve hemorrhage-induced iron deficiency anemia, including primary or secondary gastrointestinal disease (e.g., hookworms, neoplasia, ulceration) and marked ectoparasitism. The classic hematologic picture with iron deficiency is microcytic, hypochromic anemia. Microcytosis and hypochromasia are indicated on the CBC by abnormally low MCV and MCHC values, respectively. Microcytosis and hypochromasia may also be discernible on review of a blood smear as RBCs that are abnormally small, or paler-staining because of their subnormal hemoglobin concentration, respectively. However, microscopic examination is not a reliable means of detection, especially in the case of mild abnormalities. Low hemoglobin concentration is believed to contribute to microcytosis because one of the feedback mechanisms signaling erythroid cells to stop dividing is reaching a threshold hemoglobin concentration. Abnormally low hemoglobin concentration during erythropoiesis thus results in extra cell divisions and smaller erythrocytes.

765

766

**Fig. 13-19 Common erythrocyte morphologic abnormalities. A,** Blood from a dog with a microcytic hypochromic iron-deficiency anemia was mixed with an equal volume of blood from a normal dog before blood smear was prepared. Because the hypochromic (pale-staining) cells are leptocytes ([Fig. 13-19, F](#)), they have diameters similar to normal cells even though they are microcytic cells. Wright-Giemsa stain. **B,** Echinocytes appear as erythrocytes with scalloped borders; consequently, the old term “crenation” from Latin meaning “notched” is used. Wright-Giemsa stain. **C,** Three acanthocytes with irregularly spaced, variably sized spicules in blood from a dog with hemangiosarcoma. Wright-Giemsa stain. **D,** A keratocyte, exhibiting what appears to be a ruptured “vesicle” in blood from a cat with hepatic lipidosis. Wright-Giemsa stain. **E,** A schistocyte (*left*), discocyte (*top*), and echinocyte (*bottom*) in blood from a dog with disseminated intravascular hemolysis. Wright-Giemsa stain. **F,** Two thin flat hypochromic-appearing erythrocytes (leptocytes), with increased membrane-to-volume ratios, are present in blood from a dog with severe iron-deficiency anemia. The bottom leptocyte is folded. Wright-Giemsa stain. **G,** Three codocytes in blood from a Cairn terrier with a regenerative anemia and hepatic hemochromatosis secondary to pyruvate kinase deficiency. These erythrocytes exhibit a central density or “bull’s-eye” and are often referred to as target cells. Wright-Giemsa stain. **H,** Three eccentrocytes and a discocyte (*left*) in blood from a dog with oxidant injury induced by the administration of acetaminophen. The cell at top center appears spherical with a small tag of cytoplasm and may be referred to as a pyknocyte. Wright-Giemsa stain. (**A** through **H**, From Harvey JW: Atlas of veterinary hematology: blood and bone marrow of domestic animals, Philadelphia, 2001, Saunders.)

Other causes of decreased erythropoiesis include the following:

- Malnutrition
- Decreased hormonal stimulation
- Infection of erythropoietic cells
- Toxic insult to the bone marrow
- Other disease involving the bone marrow
- Immune-mediated destruction of erythroid precursors
- Inherited conditions

766

767

Specific examples of diseases causing nonregenerative anemia by these mechanisms are discussed later in this chapter. It is important to point out that nonregenerative anemia is not always caused by decreased erythropoiesis. For instance, immune-mediated hemolytic anemia (IMHA) is typically strongly regenerative, but there are also nonregenerative forms of IMHA. Bone marrow findings in dogs with severe nonregenerative immune-mediated hemolytic anemia range from a complete absence of erythropoiesis, known as pure red cell aplasia, to erythroid hyperplasia in a majority of patients in one study. The latter situation is an example of ineffective hematopoiesis (in this case, ineffective erythropoiesis), in which cells are being produced at normal or increased levels but are destroyed, presumably because of an immune-mediated mechanism, before they enter the circulation.

### 13.1.2.1.3.1.2

#### Neutropenia.

*Neutropenia* refers to a decrease in the concentration of neutrophils in circulating blood (usually expressed as cells  $\times 10^3/\mu\text{L}$ ). Neutropenia may be due to decreased production, increased destruction, altered distribution, demand for neutrophils in inflamed tissue that exceeds the rate of granulopoiesis, or inherited disease. Decreased production is evident on bone marrow examination as granulocytic hypoplasia. This usually results from an insult that affects multiple hematopoietic lineages, such as chemical insult, radiation, neoplasia, infection, and fibrosis, but may also be due to a process that preferentially targets granulopoiesis. Immune-mediated neutropenia is a rare but recognized condition in veterinary literature. Bone marrow findings can range from granulocytic aplasia or hypoplasia to hyperplasia, depending on where the cells under immune attack are in their differentiation programs. Neutropenia with no evidence of decreased production, and in which other causes of neutropenia have been excluded, may be due to destruction of neutrophils before they leave the bone marrow, a condition known as ineffective granulopoiesis. Like other forms of ineffective hematopoiesis, this condition is often presumed to be immune mediated or, in cats, a result of infection of hematopoietic cells with the feline leukemia virus.

In marked contrast to erythrocytes, neutrophils have a very short life span in circulation. Once released from the bone marrow, a neutrophil is only in the blood stream for hours before migrating into the tissues. The fate of neutrophils after they leave the blood stream in normal conditions (i.e., not in the context of inflammation) is poorly understood. They migrate into the gastrointestinal and respiratory tracts, liver, and spleen and may be lost through mucosal surfaces or undergo apoptosis and be phagocytosed by macrophages. When neutrophil production ceases, a reserve of mature neutrophils in the bone marrow (discussed in more detail later) may be adequate to maintain normal numbers of circulating neutrophils for a few days; however, after the bone marrow storage pool is depleted, neutropenia rapidly ensues.

Neutrophils within the blood vasculature may be considered to consist of two compartments: a circulating pool, consisting of those cells flowing freely in the blood, and a marginated pool, consisting of those cells transiently associated with the endothelial surface. Circulating neutrophils are part of the blood sample collected during routine venipuncture and are thus counted in the CBC, whereas marginated neutrophils are not. (In reality, neutrophils are constantly shifting between these two pools, but the proportion of cells in either pool normally remains fairly constant in any given species.) *Pseudoneutropenia* refers to the situation in which there is an increased proportion of neutrophils in the marginated pool. This may occur because of decreased blood flow or in response

## Pathologic Basis of Veterinary Disease, 4th Edition

---

to stimuli, such as endotoxemia, that increase expression of molecules promoting interaction between neutrophils and endothelial cells.

Neutropenia may also result from increased demand for neutrophils in the tissue. How rapidly such a situation develops depends not only on the magnitude of the inflammatory stimulus but also on the reserve of postmitotic neutrophils in the bone marrow. The size of this reserve, or storage pool, is species dependent. In dogs, this pool contains the equivalent of 5 days normal production of neutrophils. Cattle represent the other extreme in that they have a small storage pool, and thus are predisposed to becoming neutropenic more easily than are dogs. Horses and cats are somewhere between the two extremes, closer to cattle and dogs, respectively. It stands to reason that the clinical significance of neutropenia because of a supply and demand imbalance is also species dependent. In dogs, neutropenia due to inflammation is an alarming finding because it is evidence of a massive tissue demand for neutrophils that has exhausted the patient's storage pool and is exceeding the rate of granulopoiesis in the bone marrow, whereas in cows, neutropenia is commonly noted in a wide range of conditions involving acute inflammation and does not necessarily indicate an overwhelming demand.

13.1.2.1.3.1.3

### Eosinopenia/basopenia.

In many laboratories, CBC reference values for eosinophils and basophils are as low as zero cells per microliter, precluding detection of eosinopenia or basopenia. When detectable, eosinopenia is often part of a stress (glucocorticoid-mediated) leukogram.

767

13.1.2.1.3.1.4

### Thrombocytopenia.

768

*Thrombocytopenia* refers to a decrease in the concentration of circulating platelets. Mechanisms of thrombocytopenia include decreased production, increased destruction, increased consumption, altered distribution, and hemorrhage. Decreased production may occur because of a condition affecting cells of multiple hematopoietic lineages, including platelets, or to one specifically depressing thrombopoiesis. In either case, decreased thrombopoiesis is evident on examination of a bone marrow sample as megakaryocytic hypoplasia. General causes of decreased hematopoiesis outlined earlier in the sections on anemia and neutropenia also apply to thrombocytopenia. Specific diseases causing thrombocytopenia will be covered later in this chapter. Immune-mediated thrombocytopenia is a fairly common disease in dogs and may also occur in other species. Increased consumption of platelets is a hallmark of disseminated intravascular coagulation (DIC), a syndrome in which hypercoagulability leads to increased consumption of both platelets and coagulation factors in the plasma, with subsequent hypocoagulability and susceptibility to bleeding. The spleen normally contains a significant proportion of total platelet mass (up to one third in some species), and abnormalities involving the spleen may result in changes in the number of circulating platelets. For example, splenic congestion may result in thrombocytopenia, and splenic contraction may result in thrombocytosis. Acute hemorrhage may result in mild to moderate thrombocytopenia. Potential mechanisms of thrombocytopenia due to hemorrhage include loss and consumption. Of course, thrombocytopenia can also be a cause of hemorrhage. In the absence of other complicating factors, marked to severe thrombocytopenia (less than 50,000 platelets/ $\mu$ L) is much more likely to be the cause of, rather than the result of, bleeding. Megakaryocytic hyperplasia on examination of a bone marrow sample is evidence of a regenerative thrombopoietic response, and an increase in the mean platelet volume (MPV) value on the CBC often accompanies such a response.

## Pathologic Basis of Veterinary Disease, 4th Edition

13.1.2.1.3.1.5

### Lymphopenia.

*Lymphopenia* refers to a decrease in the concentration of lymphocytes in blood circulation. It is a common CBC finding in sick animals. Usually the precise mechanism of lymphopenia is not clear. It is often presumed to be mediated at least in part by endogenous glucocorticoid excess. Lymphopenia may occur because of various mechanisms, including altered distribution of lymphocytes (increased trafficking of lymphocytes to, and decreased egress from, lymphoid tissues), lymphotoxicity (direct damage to lymphocytes or suppression of lymphopoiesis) of therapeutic or infectious agents, loss of lymphocyte-rich lymphatic fluid, or congenital disorders. Normal lymphocyte trafficking may be altered because of disruption of the normal architecture of lymphoid tissue (e.g., because of neoplasia or inflammation), or in response to cytokine signals. Glucocorticoid excess may cause lymphopenia via redistribution from the blood to lymphoid tissue, or via direct lymphotoxic effects. Anticancer treatments (chemotherapy or radiotherapy) and immunosuppressive drugs may also be lymphotoxic. Some hereditary immunodeficiencies (such as severe combined immunodeficiency or thymic aplasia) can cause lymphopenia.

13.1.2.1.3.2

### Increased cell concentration

Increases in the concentration of many blood cells are indicated by the suffix, *-osis* (erythrocytosis, lymphocytosis, monocytosis, and thrombocytosis). Increases in granulocytes are indicated by the suffix, *-philia* (neutrophilia, eosinophilia, basophilia). Basic mechanisms causing increases in the concentration of blood cells vary considerably according to cell type, and are discussed in more detail later. Neoplasia can result in increased or decreased numbers of blood cells. In many kinds of hematopoietic neoplasia, especially leukemias, there are readily detectable numbers of neoplastic cells in the blood. Specific types of hematopoietic neoplasia are discussed later in this chapter. Increased concentrations of blood cells can also occur secondary to many forms of neoplasia (i.e., as a paraneoplastic syndrome), because of production of stimulatory cytokines by the tumor.

Veterinary laboratories typically provide species-specific hematology reference values based on a reference population of clinically normal adult animals. However, it is important to note that what is normal may vary not only between species but also as a function of other factors, such as age, breed, geographic location, and differences in laboratory methodology.

13.1.2.1.3.2.1

### Erythrocytosis.

An increase in the measured red cell mass above the normal range (i.e., the opposite of anemia) is known as erythrocytosis. The term *polycythemia* is often used interchangeably with erythrocytosis, but technically, and for the purposes of this chapter, *polycythemia* refers to a specific type of leukemia called primary erythrocytosis or polycythemia vera. Relative erythrocytosis occurs most frequently because of dehydration, when the decreased proportion of water in the blood results in hemoconcentration. A similar situation may occur as a result of epinephrine-mediated splenic contraction. Erythrocytosis due to splenic contraction occurs to the most pronounced degree in the horse, and may occur to a lesser extent in other species. In both of these cases, the total red blood cell mass is not in fact increased, but appears to be so because of other factors. *Secondary erythrocytosis* refers to a true, Epo-mediated increase in red cell mass, either as an appropriate response to hypoxemia (such as may be seen in patients with cardiopulmonary disease and severely impaired oxygenation, or cardiovascular defects causing right-to-left shunting) or in rare cases an

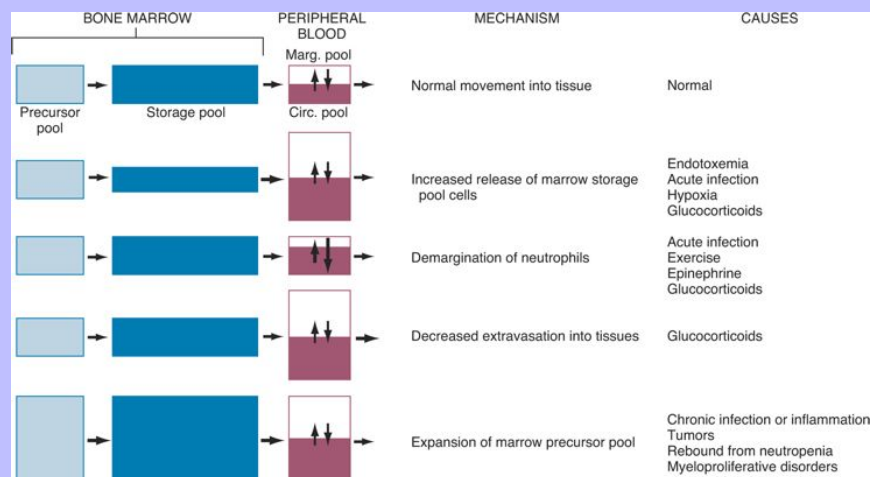

768

769

## Pathologic Basis of Veterinary Disease, 4th Edition

Epo-secreting tumor (inappropriate secondary erythrocytosis). Polycythemia vera is diagnosed based on a marked increase in red cell mass (hematocrit in normally hydrated dogs from 65% to >80%), absence of hypoxemia, absence of other tumors, and normal or decreased concentration of plasma erythropoietin concentration. Absolute erythrocytosis, whether primary or secondary, causes increased viscosity of the blood and resulting impairment of blood flow and distention of the microvasculature. Affected individuals are at increased risk of tissue hypoxia and thrombosis or hemorrhage. Related clinical signs (hyperviscosity syndrome) may include erythematous mucous membranes and prolonged capillary refill time, prominent scleral vessels, evidence of thrombosis or hemorrhage, and secondary signs (e.g., neurologic and cardiovascular) related to specific organ systems affected.

**Fig. 13-20 Schematic illustration of the mechanism of neutrophilic leukocytosis.** Neutrophils and their precursors are distributed in five pools: a bone marrow precursor pool, which includes progenitor cells and more committed, mitotically active precursors; a bone marrow storage pool, consisting of mitotically inactive mature and slightly immature neutrophils (band forms); a peripheral blood marginating pool (*Marg. pool*); a peripheral blood circulating pool (*Circ. pool*); and a tissue pool. The relative size of each pool is represented by the size of its corresponding box. The peripheral blood neutrophil count measures only the circulating peripheral blood pool, which can be enlarged by increased release of cells from the marrow storage pool, increased demargination, diminished extravasation into tissue, or expansion of the marrow precursor cell pool. (Modified from Finch SC: Hematology, ed 3, New York, 1983, McGraw-Hill.)

### Neutrophilia.

Neutrophilia occurs in response to a number of different stimuli, none of which are mutually exclusive. Major mechanisms of neutrophilia are shown in [Fig. 13-20](#). Understanding the CBC findings characteristic of these responses is an important part of clinical veterinary medicine. Inflammation can result in neutropenia, as discussed earlier, or neutrophilia, as will be discussed next. However, before moving on to a discussion of inflammatory neutrophilia and the so-called left shift, it is important to mention two other common causes of neutrophilia.

Glucocorticoid excess, either because of endogenous production or exogenous administration, results in a CBC pattern known as the “stress leukogram,” characterized by the following: mature neutrophilia (i.e., increased concentration of segmented neutrophils), lymphopenia, and, especially in dogs, monocytosis. Eosinopenia is another feature of the stress leukogram, although in many situations this is inapparent because the normal reference values for eosinophils are so low (in some laboratories, the lower reference value is zero). Mechanisms contributing to glucocorticoid-mediated neutrophilia include the following:

769

770

- Increased release of mature neutrophils from the bone marrow storage pool
- Decreased margination of neutrophils within the vasculature, with a resulting increase in the circulating pool
- Decreased migration of neutrophils from the blood stream into tissues

The magnitude of neutrophilia tends to be species dependent, with dogs having the most pronounced response (up to 35,000 cells/ $\mu$ L) and, in decreasing order of responsiveness, cats (30,000 cells/ $\mu$ L), horses (20,000 cells/ $\mu$ L), and cows (15,000 cells/ $\mu$ L) having less marked responses. With long-term glucocorticoid excess, neutrophil numbers tend to normalize, whereas lymphopenia persists.

Epinephrine release results in a different pattern, known as “physiologic leukocytosis,” characterized by mature neutrophilia (like the glucocorticoid response) and lymphocytosis (unlike the glucocorticoid response). This phenomenon is short lived (<1 hour). Neutrophilia occurs primarily because of a shift of cells from the marginated to the circulating pool. Physiologic leukocytosis is common in cats (especially when they are highly stressed during blood collection) and horses, less common in cattle, and uncommon in dogs.

Of course, neutrophilia may also indicate inflammation, and inflammatory stimuli of varying magnitude and duration produce different patterns of neutrophilia. A classic hematologic finding in patients with increased demand for neutrophils is the presence of immature forms in the blood, known as a “left shift.” Not all inflammatory responses have a left shift, but the presence of a left shift almost always signifies active demand for neutrophils in the tissue. The magnitude of a left shift is assessed by the number of immature cells and their degree of immaturity. The mildest form is characterized by increased numbers of band neutrophils, the immediate predecessor to the segmented neutrophil normally found in circulation, with increasingly severe forms involving progressively immature predecessors. A left shift is considered orderly if the number of immature neutrophils in circulation decreases as they become progressively immature. The term “degenerative left shift” is sometimes used to describe cases where the number of immature forms exceeds the number of segmented neutrophils. As with glucocorticoid-mediated neutrophilia, the typical

## Pathologic Basis of Veterinary Disease, 4th Edition

---

magnitude of neutrophilia due to inflammation varies by species, with dogs having the most pronounced response.

Marked neutrophilia may also occur because of an inherited condition known as leukocyte adhesion deficiency (LAD), in which leukocytes lack normal expression of an adhesion molecule required for migration from the blood stream into the tissue. This condition is described further in the section on specific diseases.

It might be useful to think of neutrophil kinetics in terms of a producer-consumer model in which the bone marrow is the factory, and the tissues (where the neutrophils eventually go) are the customers. The bone marrow storage pool is the factory inventory, the neutrophils in the blood stream are in delivery to the customer. Within the blood vessels, circulating neutrophils are on the highway, with margined neutrophils temporarily pulled off to the side of the road. During health, there is an even flow of neutrophils from the factory to the customer. Thus the system is in steady state, and neutrophil numbers remain relatively constant and within the normal range. However, disease states may perturb this system at multiple levels. Decreased granulopoiesis is analogous to a factory working below normal production level. Ineffective granulopoiesis is analogous to goods being damaged during manufacturing and never leaving the factory. A left shift is analogous to the factory meeting increased customer demand by shipping out unfinished goods. Cases of persistent, established inflammation are characterized by bone marrow granulocytic hyperplasia and mature neutrophilia, analogous to a factory that has had time to adjust to increased demand and is meeting it more efficiently by increasing its output.

13.1.2.1.3.2.3

### Eosinophilia/basophilia.

Eosinophilia and, less commonly, basophilia (which, when present, often occurs in tandem with eosinophilia) may occur in response to parasitism, as part of an allergic response, as a paraneoplastic abnormality (because of production of cytokines by neoplastic cells or other inflammatory cells reacting to the neoplasm), or as an atypical response to nonparasitic infectious disease.

13.1.2.1.3.2.4

### Thrombocytosis.

Thrombocytosis, or concentration of platelets in the blood above normal reference values, is a relatively common nonspecific finding in veterinary patients. In the vast majority of cases, thrombocytosis is reactive—a response to another, often apparently unrelated, disease process. Examples of conditions associated with reactive thrombocytosis include inflammatory and infectious diseases, iron deficiency, hemorrhage, endocrinopathies, and neoplasia. Factors that may contribute to reactive thrombocytosis include increased plasma concentration of thrombopoietin, inflammatory cytokines (e.g., IL-6), or catecholamines. Thrombocytosis may also occur as part of a regenerative response in patients recovering from thrombocytopenia, or as a result of redistribution because of splenic contraction (especially in horses) or splenectomy. In these cases, thrombocytosis is transient. In the case of splenectomy, thrombocytosis may be marked, but normalizes after several weeks. Because the body's total platelet mass regulates thrombopoiesis, and a significant portion of the platelet mass is normally in the spleen, it makes sense that splenectomized animals develop thrombocytosis. However, the reason that the number of circulating platelets normalize in these individuals in the weeks after splenectomy is not clear. There is also a rare form of leukemia known as essential thrombocythemia, which is characterized by marked thrombocytosis.

770

771

### Lymphocytosis.

*Lymphocytosis* refers to an increase in the concentration of lymphocytes in blood circulation. There are numerous causes of lymphocytosis. Young animals normally have higher numbers of lymphocytes than older animals, and normal healthy young animals may have counts that exceed adult reference values. As discussed earlier in the section on neutrophilia, lymphocytosis is also a feature of epinephrine-mediated physiologic leukocytosis, resulting from redistribution of lymphocytes into the blood circulating pool. Epinephrine-mediated lymphocytosis may be more marked than neutrophilia, particularly in cats (lymphocyte counts of  $>20,000/\mu\text{L}$  are not uncommon). Antigenic stimulation may result in lymphocytosis, even in rare cases in marked lymphocytosis (up to approximately 30,000 cells/ $\mu\text{L}$  in dogs, and 40,000/ $\mu\text{L}$  in cats): however, this is not usually the case, even when there is clear evidence of increased immunologic activity in lymphoid tissues. In cases of antigenic stimulation, it is common for a minority of lymphocytes to have a “reactive” morphology—larger in size than small, mature lymphocytes, and with more abundant, deeply basophilic cytoplasm and incompletely condensed chromatin (Fig. 13-21). Just as glucocorticoid excess can cause lymphopenia, glucocorticoid deficiency (hypoadrenocorticism) can cause lymphocytosis, or lack of lymphopenia under conditions of stress that typically result in glucocorticoid-mediated lymphopenia.

**Fig. 13-21 Lymphocytes, canine blood smear.** **A**, Small lymphocytes, the predominant type of lymphocyte in the blood under normal conditions. **B**, A reactive lymphocyte, characterized by mildly increased size and an increased amount of basophilic cytoplasm, from a recently vaccinated 16-week-old dog. ## Pathologic Basis of Veterinary Disease, 4th Edition

---

A condition known as persistent lymphocytosis (PL) occurs in approximately 30% of cattle infected with the bovine leukemia virus (BLV). The condition is defined as an increase in the blood concentration of lymphocytes above the reference interval for at least 3 months. This form of lymphocytosis is a nonneoplastic proliferation (hyperplasia) of B lymphocytes. In the absence of other disease, cattle with PL are asymptomatic. However, cattle infected with BLV, especially those animals with PL, are at increased risk to develop B-lymphocyte lymphoma. (BLV and lymphoma in cattle are discussed in more detail later in this chapter in the section on hematopoietic neoplasia.) As in most other forms of benign lymphocytosis, the morphology of most lymphocytes is within normal limits in cattle with PL.

13.1.2.1.4

### Abnormal Structure or Function in Response to Injury

The preceding section focused on abnormalities in the number of blood cells. There are also various acquired and inherited conditions involving abnormal structure or function of hematopoietic cells or components of hemostasis. Primary disorders of blood cells and hemostasis are discussed later in the chapter in the section on specific diseases. However, abnormal structure or function may reflect disease and cause it. For example, morphologic abnormalities detected on routine microscopic examination of blood smears may provide important clues about underlying disease processes. Poikilocytosis is a broad term referring to the presence of abnormally shaped erythrocytes in circulation. [Table 13-2](#) lists conditions associated with and mechanisms involved in the formation of a number of specific types of erythrocyte morphologic abnormalities, and [Fig. 13-18](#) shows some examples. There are also some structural and functional abnormalities of erythrocytes that are not pathologic. For example, Japanese breed dogs (Akitas and Shibas) have erythrocytes that are smaller than normal. Erythrocytes in these breeds also have a high concentration of potassium, unlike erythrocytes in other dog breeds.

771

772

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 13-2 Common Erythrocyte Morphologic Abnormalities

Term	Description	Condition(s) Commonly Associated with Increased Numbers of Abnormal RBCs
Macrocyte	Abnormally large	Regenerative anemia FeLV infection (cats) Congenital in some poodle dogs
Microcyte	Abnormally small	Iron Portosystemic shunts Normal in Akita and Shiba dogs
Polychromasia	Bluish color (Figs. 13-5, 13-12, 13-17)	Reticulocytosis (regenerative anemia)
Basophilic stippling	Fine punctate inclusions (Fig. 13-12)	Lead toxicity Regenerative anemia (especially ruminants)
Howell-Jolly body (nuclear remnant)	Small, round, blue-black inclusion, usually off-center (Fig. 13-17)	Regenerative anemia Splenic dysfunction
Hypochromasia	Increased pallor and deformability (Fig. 13-19)	Iron deficiency
Heinz body	Pale round inclusion, may bulge from cell margin; stains blue with new methylene blue (Fig. 13-18)	Oxidative damage
Poikilocyte	Nonspecific term for shape abnormality—specific types of poikilocytosis listed below	See below
Spherocyte	Appears abnormally small with uniform staining (Fig. 13-17)	Extravascular hemolysis
Schistocyte	Small, irregular RBC fragment, often crescent shaped (Fig. 13-19)	Microangiopathies (e.g., DIC, hemangiosarcoma, glomerulopathy) Increased RBC deformability (e.g., iron deficiency)
Acanthocyte	Few irregular projections (Fig. 13-19)	Abnormal lipid metabolism (e.g., liver disease) Microangiopathies (as per schistocytes) Increased RBC deformability (as per schistocytes) Common normal finding in young goats
Echinocyte	Many relatively uniform projections (Fig. 13-19)	Usually in vitro artifact Normal in pigs
Eccentricocyte	Eccentric staining (Fig. 13-19)	Oxidative damage
Leptocyte	Thin, often hypochromic and/or folded (Fig. 13-19)	Iron deficiency
Codocyte ("target cell")	Area of dense staining within central pallor (Fig. 13-19)	Liver disease
Keratocyte	Intact or ruptured "blister" (Fig. 13-19)	Liver disease Conditions causing schistocytosis and/or acanthocytosis

DIC, Disseminated intravascular coagulation; FeLV, feline leukemia virus; RBC, red blood cell.

Similarly the acquired neutrophil morphologic abnormality known as toxic change (Fig. 13-22) reflects accelerated production of neutrophils as part of the inflammatory response. Features of toxic change include increased cytoplasmic basophilia, the presence of small blue-gray cytoplasmic inclusions known as Döhle bodies (often noted incidentally in cats), and in more severe cases, cytoplasmic vacuolation.

Although not associated with impaired neutrophil function, toxic change occurs during granulopoiesis and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

thus is technically a form of dysplasia (e.g., Döhle bodies are foci of aggregated endoplasmic reticulum). Toxic change may accompany any inflammatory response, but in general the more marked the toxic change, the higher the index of suspicion for infection or endotoxemia. There are also abnormalities of granulocytes that are not pathologic, such as the Pelger-Huët anomaly, in which granulocytes are hyposegmented ([Fig. 13-33](#)).

**Fig. 13-22 Toxic change, neutrophils, canine blood smear.** Two band neutrophils with basophilic, foamy cytoplasm indicate toxic change. This dog also has reactive thrombocytosis. Wright's stain. (Courtesy Dr. M.M. Fry, College of Veterinary Medicine, University of Tennessee.)

Structural or functional abnormalities of blood vessels, platelets, or coagulation factors may result in a tendency toward hypocoagulability (bleeding), hypercoagulability (inappropriate thrombosis), or both. In veterinary medicine, there has been a great deal of work on specific mechanisms of hypocoagulability, whereas mechanisms of hypercoagulability are less fully characterized. Disorders of primary hemostasis typically result in “small bleeds” (e.g., petechiation, mild ecchymosis, bleeding from mucous membranes, bleeding immediately after venipuncture), whereas disorders of secondary hemostasis typically result in “big bleeds” (e.g., hemorrhage into body cavities/joints, marked ecchymosis, large hematomas, delayed bleeding after venipuncture). This chapter concentrates on primary disorders of hemostasis, and also covers the secondary condition known as disseminated intravascular coagulation, or DIC. However, it is important to note that coagulation disorders can also result from other underlying disease processes. For example, advanced liver disease can lead to abnormal hemostasis through decreased or defective synthesis of coagulation factors, or impaired clearance of fibrinolytic products that inhibit coagulation reactions and platelet function. Vascular disorders may also result in a bleeding tendency, because of abnormalities of endothelial function or collagen-platelet interactions. Specific diseases involving abnormal structure or function of hematopoietic or hemostatic elements are discussed later in this chapter.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 13.1.2.2 LYMPHATIC SYSTEM

#### 13.1.2.2.1 Thymus

The responses of the thymus to injury are shown in [Box 13-3](#). The most common change is lymphoid atrophy caused by physical and physiologic stresses, toxins, drugs, and viral infections. Causes of lymphoid atrophy are shown in [Box 13-4](#). Atrophy must be differentiated from normal involution. Inflammation is rare and primary malignant tumors are uncommon. Enlargement of the thymus is relatively rare and is usually the result of neoplasia. Occasionally, it can be the result of hematomas. Inflammation of the thymus is rare. Porcine circovirus 2, the etiologic agent of postweaning multisystem wasting syndrome in pigs, causes a granulomatous thymitis, chiefly affecting the medulla and also granulomatous inflammation of other lymphoid organs. Porcine circovirus 2 is an unusual virus in that it causes a granulomatous response. A diffuse infiltration of inflammatory cells into the thymus has also been reported in salmon poisoning disease of dogs and in epizootic bovine abortion.

13.1.2.2.2

### Spleen

The response of spleen to injury (Box 13-5) is a reflection of its three anatomic components: (1) monocyte-macrophage system, (2) lymphoid (immune) system, and (3) vasculature, chiefly the red pulp vascular spaces.

773

13.1.2.2.2.1

### Monocyte-macrophage system

The spleen is a major site of cells of the monocyte-macrophage system, and these are responsible for “filtering” the blood through phagocytosis of bacteria, immune complexes, and altered cells, such as senescent erythrocytes and those containing hemotropic parasites (e.g., *Babesia*). Thus the spleen is able to mount a very strong response to blood-borne pathogens. In immunized rabbits injected intravenously with pneumococci, the blood was cleared of 98% of those bacteria within 15 minutes, and 100% of an inoculum of 1 billion bacteria was removed from the blood within an hour. Also the

774

## Pathologic Basis of Veterinary Disease, 4th Edition

---

spleen removed 10 times the number of bacteria per gram as the liver. When 1 billion pneumococci per pound of body weight were injected into the splenic artery of a dog over a 5-minute period, all bacteria were removed from the blood in 65 minutes. After splenectomy, blood-borne organisms multiply rapidly and are disseminated widely in the body. Also it has been shown that the phagocytic function of the spleen is critical in the control of plasmodium and *Babesia* in human beings, and the same is true of hemotropic parasites in animals, for example in babesiosis in cattle. To facilitate filtering, all of the blood in the body passes through the spleen at least once in a day.

Sometimes the number of pathogenic bacteria arriving via the circulation at the spleen can be so large that it exceeds its capacity to overcome them immediately. The result will be abscesses or granulomas, depending on the microorganism, usually abscesses in response to bacteria, and granulomas in response to fungi and those bacteria that are intracellular facultative pathogens of macrophages (e.g., *Mycobacterium bovis*).

13.1.2.2.2.2

### Lymphoid component of the spleen

The spleen is also a secondary lymphoid organ, the site of immune responses. The response of the white pulp (PALS and splenic follicles) is either hyperplasia or atrophy. Hyperplasia occurs in response to antigenic stimuli and results in the formation of antibodies, which are released into the efferent lymph and blood where they are available to combat hematogenously borne agents, including those arriving in the spleen. Atrophy occurs in response to lack of antigenic stimulation, toxins, antineoplastic chemotherapeutic agents, viruses, radiation, malnutrition, age, and wasting/cachectic diseases.

13.1.2.2.2.3

### Vascular component of the spleen

Because of the contractility of the splenic capsule and trabeculae in the spleens of domestic animals, the spleen may either expand to store blood, or contract and expel the “reserve” of blood. Thus they may be either grossly enlarged and congested or small with a wrinkled surface and a dry parenchyma (see Uniform Splenomegaly and Small Spleens).

13.1.2.2.2.4

### Lymph nodes

Like the spleen, lymph nodes contain elements of the monocyte-macrophage system and the lymphoid system, and their responses are similar (Box 13-6). Cells of the monocyte-macrophage system are the first line of defense against noxious agents. As most of these agents arrive in the afferent lymph, the sinus macrophages (histiocytes) are the first to respond. This is evidenced by an increase in their number (so-called sinus histiocytosis) in the subcapsular, trabecular, and medullary sinuses (Fig. 13-23). Additional inflammatory cells (e.g., neutrophils and monocytes) arrive in the blood and migrate to the parenchyma or into the sinuses.

Also, antigens from incoming material will be presented to cells of the germinal centers, which will produce immunoblasts that migrate to the medullary cords, mature into plasma cells, and secrete a specific antibody. The antibody will leave the lymph node through the efferent lymphatics, enter the blood circulation as a plasma protein, and be recirculated to the lymph node.

To understand the response of a lymph node, it is helpful to consider how molecules and cells arrive. This is accomplished in one of two ways: in the incoming lymph delivered by the afferent lymphatics

## Pathologic Basis of Veterinary Disease, 4th Edition

---

to the subcapsular sinus or via the arterial blood supply. T lymphocytes arrive by the latter route and migrate out of the high endothelial venules into the T-lymphocyte areas adjacent to the follicle (see [Chapter 3](#)). Particles and molecules in the lymph arriving at the lymph node enter the subcapsular sinus. Here hydrostatic pressure is low and particles tend to settle, facilitating phagocytosis by the sinus macrophages. Recent work has indicated that the pathway of particles and molecules whose diameters are greater than approximately 7 nm is different from that of molecules smaller than this. Larger molecules and particles flow from the subcapsular into the trabecular sinuses and then into the medullary sinuses, where particles and bacteria are phagocytosed by the sinus histiocytes. This is well illustrated by the concentration of carbon in the medulla of the tracheobronchial lymph nodes of animals with anthracosis.

774

775

Acute—microabscess and abscess formation

Chronic—abscesses and granulomas

**Fig. 13-23 Sinus histiocytosis, lymph node, medulla, dog.** The sinuses (1) are filled with mostly macrophages and a few scattered neutrophils (small dark nuclei). Most of the macrophages are derived from the perisinusoidal macrophages, but some may arrive via the afferent lymphatics. The medullary cords (2) are filled with lymphocytes and plasma cells. Plasma cell precursors are formed in the germinal centers, mature into plasma cells, and migrate to the medullary cords. Thus the presence of large numbers of plasma cells in the medullary cords is indicative of ongoing production of antibody from an antigenic stimulus. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Lymph-borne soluble factors, such as chemokines, penetrate the floor of the subcapsular sinus and are carried along reticular fibers to the high endothelial venules, which is the site of migration of T lymphocytes into the cortex, thus bringing these molecules into close association with T lymphocytes and facilitating the production of specific antibodies from B lymphocytes.

### 13.1.2.2.3

#### Lymphoid Nodules

The response of lymphoid nodules ([Box 13-7](#)) is similar to that of splenic and lymph node follicles. Thus with antigenic stimulation, there will be follicular hyperplasia, activation of germinal centers, and increased production of antibodies. The BALT can become markedly hyperplastic in chronic infections as in *Dictyocaulus* bronchitis or bronchiolitis in cattle, sheep, and goats; *Metastrongylus* bronchitis or bronchiolitis in pigs; and *Mycoplasma* bronchiolitis in calves. Hyperplastic lymphoid nodules can be so enlarged that they become grossly visible as white plaques or nodules (in the conjunctiva of the eyelids and the third eyelid as in chronic conjunctivitis [[Fig. 13-24](#)] and in the pharyngeal mucosa in chronic

## Pathologic Basis of Veterinary Disease, 4th Edition

pharyngitis). Presumably the enlargement of these lymph nodules from follicular hyperplasia is a reflection of the chronicity of the disease.

Atrophy of lymphoid tissues has the same causes as those affecting lymph nodes. These include lack of antigenic stimulus, cachexia, malnutrition, aging, and viral infections. The microscopic lesions of BVD infection of Peyer's patches are distinctive and consist of lysis of the cells of the lymphoid follicles.

Invading cells or microorganism gain access to the bone marrow or blood circulation either hematogenously or by trauma. Trauma may be as obvious as a gaping wound or as subtle as the bite of an insect.

### 13.1.3.3 LYMPHATIC SYSTEM

#### 13.1.3.3.1 Thymus

Toxic agents, such as aflatoxins and viruses, enter the thymus hematogenously.

#### 13.1.3.3.2 Spleen

Noxious agents such as bacteria enter the spleen by two routes: hematogenously or by direct penetration. The spleen has no afferent lymphatics, and so this is not a possible route of entry of infection. Direct penetration is extremely rare. The capsule is thick, and thus inflammation from an adjacent peritonitis is unlikely to penetrate it. However, foreign bodies occasionally do. This is seen as a sequela to traumatic reticulitis in cattle, where a foreign body, usually a nail or wire is extruded through the left caudal reticulum wall by its contraction and enters the visceral surface of the ventral extremity of the spleen and often causes a splenic abscess. Most of these extruded foreign bodies usually travel cranially to penetrate the diaphragm and pericardium, causing traumatic reticulopericarditis. In horses, on rare occasions, splenic abscesses can develop secondary to perforation of the gastric wall. This can be caused by gastric ulcers, *Gasterophilus intestinalis*, or by extension on the granulomatous inflammation around *Habronema* in the wall of the stomach.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 13.1.3.3.3 Lymph Nodes

Noxious agents, including bacteria, viruses, and antigens, enter the lymph node by two routes: afferent lymphatics and the blood.

#### 13.1.3.3.3.1 Afferent lymphatics

Noxious agents are transported in lymph to the regional lymph node or lymphocenter. Here some of these agents may escape removal by phagocytosis in that lymph node and then be transported in the efferent lymph to the next lymph node in the chain, where they can cause an inflammatory or immunologic response. If they are not removed by any of the lymph nodes in the chain, noxious agents may be eventually transported via the lymphatics to the circulating blood.

#### 13.1.3.3.3.2 Blood

Agents can arrive hematogenously in septicemias and bacteremias. However, most pathogens arrive at lymph nodes via the afferent lymphatics.

#### 13.1.3.3.3.3 Capsule

The lymph node is protected by a thick fibrous capsule, and thus direct penetration by inflammation, trauma, or neoplasms is extremely rare.

#### 13.1.3.3.4 Lymphoid Nodules

Lymphoid nodules also respond to antigens arriving hematogenously, but in many cases the agent or antigens will cross the mucous membrane, for example in chronic inflammation of nasal, oral, bronchial, gastrointestinal, or conjunctival mucous membranes. As described previously, M cells of Peyer's patches can transport infectious agents.

### 13.1.4 METHODS FOR GROSS AND MICROSCOPIC EXAMINATION

#### 13.1.4.1 BONE MARROW AND BLOOD CELLS

Routine diagnostic testing often provides great insight into disorders of the hematopoietic system. The complete blood count (CBC) is a cornerstone of diagnosis, part of routine evaluation of any sick patient. The CBC includes not only numerical data indicating the concentration of different cell types and hemoglobin in the blood, but also information gleaned from microscopic review of a blood smear, such as cell morphology and the presence of hemoparasites. (Note: Some parasites may be detected within blood cells, such as *Hepatozoon* organisms within circulating neutrophils or monocytes, but they mainly cause disease in other body systems and are therefore not discussed in this chapter.) Learning to evaluate blood smears is a valuable skill for any practicing veterinarian. The CBC also reports plasma protein concentration as measured with a refractometer. It is important to remember that changes in hydration status, and in the distribution of body fluids between the vascular and extravascular compartments, affect the concentration of both cells and proteins in the blood.

776

777

### Other Tests Used to Evaluate the Hematopoietic System

Other tests include the following:

- Bone marrow examination (aspiration or core biopsy). This is usually done to assess hematopoiesis when a patient has unexplained cytopenia(s) or atypical cells in circulation but also to look for neoplasia or, occasionally, infection. Preferred sites for collecting bone marrow samples are: in horses, the sternum; in cattle, the proximal ribs; and in dogs and cats, the proximal humerus, iliac crest, or proximal femur. Normal hematopoietic cellularity of the marrow is age-dependent (recall that the amount of fat increases with age). Cytologic evaluation of a Wright's-stained, air-dried smear of a bone marrow aspirate is the preferred method for evaluating cellular detail and in most cases provides a good estimate of overall marrow cellularity. Histopathologic evaluation of a hematoxylin and eosin (H&E) stained core biopsy is the most reliable way to assess marrow cellularity, because tissue architecture is preserved. In either case, bone marrow findings can only be interpreted fully along with a concurrent CBC. (Note: Hematopoietic tissue is highly susceptible to autolysis. This is more of a limitation with regard to cytology than histology. Postmortem samples are often not suitable for cytologic interpretation unless collected immediately [i.e., within minutes after death].) Bone marrow examination yields information about the production of cells of specific lineages (i.e., erythropoiesis, granulopoiesis, and thrombopoiesis) in addition to the overall cellularity of the marrow. Increased production is evident as hyperplasia; decreased production as hypoplasia. The proportion of different cell types varies somewhat by species, but as a rule there are similar numbers of erythroid and myeloid (granulocytic and monocytic) nucleated cells, and much higher numbers of late-stage than early-stage cells. The amount of iron in the marrow can also be estimated by microscopic examination. Hemosiderin, a water-insoluble form of storage iron (less readily accessible than ferritin, which is soluble), is found mainly in macrophages in the marrow, spleen, and liver, and appears as coarse yellow-brown granular material with routine stains. Staining the sample with an iron-specific stain, such as Prussian blue, can make it easier to assess marrow iron stores. Cats differ from other species in that their marrow normally does not contain stainable iron.
- Aspiration cytology and/or histopathology of other organs (e.g., to assess extramedullary hematopoiesis, increased destruction of erythrocytes, neoplasia, or infection). Evaluation of lymph nodes and spleen is discussed later.
- Tests to detect an autoantibody bound to the cell surface. The Coombs' test, or direct antiglobulin test, is the standard assay for immune-mediated hemolytic anemia. Flow cytometry and immunofluorescent antibody tests may also be used to detect autoantibody bound to erythrocytes or other cells.
- Immunophenotyping to identify cells based on expression of characteristic molecules (markers). Immunophenotyping may be done by immunohistochemistry, immunocytochemistry, or flow cytometry.
- Polymerase chain reaction (PCR) assays for infectious agents or clonal lymphocyte proliferations.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 13.1.4.2 HEMOSTASIS

The CBC provides basic information about platelets, including numeric values for platelet concentration and mean platelet volume (MPV), subjective assessment of platelet morphology (size, shape, and granularity), and a rough estimation of platelet numbers based on examination of a blood smear. Some laboratories measure reticulated platelets (platelets recently released from the bone marrow), although this test is mostly used in the research setting at present. Increased MPV and increased numbers of reticulated platelets tend to indicate increased thrombopoiesis. Bone marrow examination is indicated with any unexplained cytopenia, including thrombocytopenia, to evaluate production.

Tests to evaluate the components of the hemostatic process are described and listed in [Appendix 13-1](#) at the end of this chapter.

### 13.1.4.3 LYMPHATIC SYSTEM

#### 13.1.4.3.1 Thymus

Because the thymus involutes after sexual maturity, evaluating whether it is smaller than normal is difficult, unless the change is extreme or age-matched control animals are available. Before sexual maturity, the thymus is easily identified as a lobular organ, white to gray with a thin capsule. After sexual maturity, the gland is often indistinguishable from adipose connective tissue within the cranial mediastinum. An extremely small thymus in a neonatal animal should be considered abnormal and an indicator of a possible underlying primary or acquired immunodeficiency. Enlargement of the thymus is almost always due to tumors. The cut surface should be examined for tumors and hematomas.

777

#### 13.1.4.3.2 Spleen

778

Spleens can be enlarged (splenomegaly), normal in size, or small. They can be uniform in shape or have a “lumpy-bumpy” to nodular surface. The appearance of the surface of the spleen varies among species of domestic animals, depending on the thickness of the capsule and consequently the visibility of the red pulp through it. In the pig, dog, and cat, the capsule is thin, and the red color of the red pulp is visible. The splenic capsules of horses and ruminants are thicker and appear gray because the color of the red pulp may not be visible through the capsule. However, if the capsule has thick and thin areas, it may be mottled gray and red.

The tenseness of the capsule of normal and diseased spleens depends on how much the splenic parenchyma is distended by stored blood or infiltrating inflammatory cells or neoplasms. Spleens devoid of stored blood can have a wrinkled surface. The spleens of ruminants have prominent trabeculae, which appear as gray bands in the red pulp. The ventral extremity of the canine spleen is expanded and is thus wider than the remainder of the spleen, which has approximately parallel sides. The parietal surface of the spleen is smooth, but the visceral surface has a longitudinal ridge, which is the hilus where arteries and veins enter and exit the spleen.

At necropsy, the pathologist has to evaluate the spleen based on whether there is splenomegaly, whether this is uniform or nodular, and whether the consistency is congested (bloody) or firm (meaty). The diseases associated with splenomegaly will be discussed using those criteria. The most common causes of splenomegaly are one or more of the following: storage of blood, increase in the cells of the

## Pathologic Basis of Veterinary Disease, 4th Edition

---

monocyte-macrophage system, lymphoid hyperplasia, inflammation, or neoplasia. Occasionally, it can be due to stored material, such as occurs in lysosomal storage diseases or from extracellular deposits, such as amyloid.

13.1.4.3.2.1

### Uniformly enlarged spleens (splenomegaly)

There are two basic types of splenomegaly: congestive and not congestive. The cut surface of severely congested spleens may be red to bluish-black and exude blood (congested or “bloody” spleens). Enlarged spleens that are not congested but firm are often called “meaty” because of their firmness and texture. Little blood oozes from their cut surfaces, and the color of this surface depends of how much of the normal red pulp has been replaced by neoplastic cells, inflammatory cells, or stored material. [Table 13-3](#) lists the common causes of uniform splenomegaly.

13.1.4.3.2.2

### Nodular spleens with or without splenomegaly

Nodular disorders are characterized by a spleen that has nodules that are randomly distributed, may be discrete or coalescent, are raised above the splenic surface, bulge from the cut surface, and have a variety of appearances and colors based on the cause of the lesion. Many of the disease processes causing a nodular splenomegaly are similar to those causing a uniform splenomegaly. Nodules can be abscesses, granulomas, hematomas, hyperplastic foci of lymphocytes, hematopoietic cells, or primary or metastatic neoplasms.

13.1.4.3.3

### Lymph Nodes

Lymph nodes should be dissected free of fat and connective tissue. Gross examination includes determining the size and whether the capsule is intact (some very highly infiltrative neoplasms extend beyond the capsule) and an evaluation of the cut surface. For the latter, the visibility of the cortex and medulla, any lack of normal architecture, and the colors should be determined. Normal architecture can be completely or partially obliterated by tumor (e.g., lymphoma [lymphosarcoma]) or by diffuse granulomatous inflammation (e.g., in blastomycosis, histoplasmosis, or cryptococcosis). The cortex can be enlarged in lymphoid hyperplasia, and in extreme follicular lymphoid hyperplasia, follicles may be visible as nodules 1 to 2 mm in diameter. Because of the notable phagocytic activity of the medullary sinus macrophages, the medulla can be colored by phagocytosed material (e.g., black from carbon in anthracosis [tracheobronchial lymph nodes] and brown from hemosiderin as a result of draining a hemorrhagic area or a site of an intramuscular iron injection).

The cut surface can be red from acute hyperemia, as in acute lymphadenitis, or the sinuses can be red from blood drained from a hemorrhagic or inflamed area. Also, the cut surface can be excessively wet when the lymph node drains an edematous area.

It is essential that enlarged lymph nodes be examined microscopically. In the live animal, this is easily accomplished by cytologic evaluation of superficial lymph nodes. Cells are collected into a 22- to 25-gauge needle with gentle aspiration using a 6- or 12-mL syringe or by a nonsuction “pincushion” technique, and then they are gently expelled onto glass slides. The fragility of lymphocytes necessitates gentle spreading to prevent cellular distortion. Aspirates are stained with a Romanowsky's stain, such as Wright's, Wright-Giemsa, or Diff-Quik. The ease of lymph node sampling and staining provides veterinary clinicians with the opportunity to become proficient in the evaluation of lymph node cytology. Also, microorganisms, such as bacteria (e.g., streptococci, corynebacteria, and rhodococci), fungi (e.g.,

## Pathologic Basis of Veterinary Disease, 4th Edition

blastomyces and cryptococci), rickettsia (e.g., *Neorickettsia helmintheca*, the agent of salmon poisoning disease), and protozoa (e.g., leishmania) can be detected.

778

779

EIA, Equine infectious anemia.

Aspirates provide excellent cellular detail, but for the study of architectural derangements, removal of the node for histologic evaluation is necessary. The surgeon must handle lymph nodes carefully to minimize artifacts. Any compression (e.g., squeezing with forceps) will cause artifacts and usually damage the nuclei. A portion of one end of the node should be removed and used to prepare impression smears. The remainder of the node should be placed in fixative fluid, with the capsule intact, for 1 hour. This period of fixation hardens the node and prevents artifactual bulging of the tissue from the cut surface when the lymph node is sliced. This is usually a problem when lymph nodes are cut without prior fixation. The lymph node, if large, should then be sliced transversely into parallel 2- to 3-mm thick sections to ensure penetration of the fixative fluid. Cross sections of lymph node are preferred because they are usually sufficiently small to allow a full cross section, including both the cortex and medulla to fit onto a

## Pathologic Basis of Veterinary Disease, 4th Edition

---

microscope slide. The exception is the porcine lymph node with its different anatomic arrangement. Because the location and amount of “cortical” and “medullary” matter varies with the direction of the cut, a longitudinal plane section is recommended as being the most representative. At a minimum, all lymph nodes should be incised at least once before being placed in a fixative; otherwise the time taken to penetrate the capsule will delay fixation.

### 13.1.4.3.3.1

#### Size of lymph nodes

Lymph nodes can be enlarged as a consequence of inflammatory (lymphadenitis) or noninflammatory (lymphadenopathy) processes. Clinically, lymph node enlargement can occur in several forms. First, all lymph nodes may be enlarged (systemic and/or generalized enlargement). This form of lymph node enlargement is generally attributed to systemic infectious, inflammatory, or neoplastic processes. If the regional lymph node (e.g., a lymph node draining one of the limbs or one side of the oral cavity) is enlarged, then infectious, inflammatory, or neoplastic processes must be considered in the area drained by that node. Finally, enlargement of the mesenteric lymph nodes or GALT suggests that the infectious, inflammatory, or neoplastic process originates within the gut.

The gross and histologic appearances of mesenteric lymph nodes are somewhat different from those of unstimulated peripheral lymph nodes. The mesenteric lymph nodes are continuously receiving a barrage of antigens and some bacteria via the afferent lymphatics, draining the gastrointestinal tract. This is reflected in their appearance. They are larger and have numerous well-developed lymphoid follicles (follicular lymphoid hyperplasia) with active germinal centers. Often the sinuses contain histiocytes (sinus histiocytosis), presumably in response to the need to phagocytose incoming material.

Enlargement of a lymph node is called lymphadenomegaly, although in common parlance it is often called lymphadenopathy. If a node(s) is congenitally small or absent, the condition is called lymph node hypoplasia or lymph node aplasia, respectively.

Enlargement may involve only an isolated lymph node, which is usually the result of a response to inflammatory products, infectious microbes, or neoplasms draining to a regional lymph node. Enlargement may also involve multiple nodes of a chain because infection or metastases spread up the lymphatics, from one lymph node to the next. Sometimes enlargement may be confined to superficial lymph nodes and on another occasion to visceral lymph nodes. Thus it is important that the clinician or prosector be familiar with the area drained by specific lymph nodes; for example, all lymph from the head drains to the medial retropharyngeal lymph nodes, and lymph from the foreleg drains to either the axillary or superficial cervical (prescapular) lymph node.

## 13.2 DISEASES OF THE BONE MARROW, BLOOD CELLS, AND LYMPHATIC SYSTEM

### 13.2.1 BONE MARROW AND BLOOD CELLS

This section focuses on diseases of bone marrow and blood cells. Some aspects of diseases covered in this section are discussed further in the Lymphatic System section later in the chapter.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 13.2.1.1 STEM CELL DISORDERS AND PANCYTOPENIC DISORDERS

#### 13.2.1.1.1 Aplastic Anemia

Aplastic anemia is a rare condition characterized by aplasia or severe hypoplasia of all hematopoietic lineages in the bone marrow and resulting pancytopenia. The term is something of a misnomer because affected cells are not limited to the erythroid lineage (see the later discussion of pure red cell aplasia, with disorders of erythrocytes). Aplastic anemia is also known more accurately as aplastic pancytopenia. Destruction of hematopoietic stem cells or progenitor cells is recognized as a cause of the condition. Other proposed mechanisms include disruption of normal stem cell function because of mutation or perturbation of the hematopoietic microenvironment.

Many of the conditions reported to cause aplastic anemia in domestic animals do so only rarely, or idiosyncratically, and more frequently cause other hematologic or nonhematologic abnormalities. A partial list of reported causes of aplastic anemia in domestic animals includes the following:

- Chemical agents
  - Antimicrobial agents (dogs, cats)
  - Chemotherapeutic agents (dogs, cats)
  - Phenylbutazone (horses, dogs)
  - Bracken fern (cattle, sheep)
  - Estrogen (dogs)
  - Trichloroethylene (cattle, sheep)
  - Aflatoxin B<sub>1</sub> (horses, cattle, dogs, pigs)
- Infectious agents
  - Ehrlichiosis (dogs, cats)
  - Parvovirus (dogs, cats)
  - Feline leukemia virus (cats)
  - Feline immunodeficiency virus (cats)
  - Equine infectious anemia (horses)
- Idiopathic (horses, cattle, dogs, cats)

Aplastic anemia occurs in both acute and chronic forms. Most of the chemical causes result in acute disease. As discussed in the earlier section on mechanisms of disease, severe neutropenia typically develops within 1 week of an acute insult to the bone marrow, after the bone marrow storage pool is

## Pathologic Basis of Veterinary Disease, 4th Edition

depleted, and severe thrombocytopenia in the second week. The development of anemia is more variable, depending in part on how rapidly the marrow recovers from the insult, and on the RBC life span of the particular species. Severe neutropenia and thrombocytopenia predispose affected individuals to infection and hemorrhage, respectively. In addition to aplasia, pathologic bone marrow findings in animals with aplastic anemia may include evidence of necrosis, degeneration of hematopoietic cells, and an increase in phagocytic macrophages. Fig. 13-25 shows bone marrow aspirates from a dog with acute 5-fluorouracil-induced pancytopenia, before and during recovery.

780

## Pathologic Basis of Veterinary Disease, 4th Edition

---

13.2.1.1.2

### Cyclic Hematopoiesis

Cyclic hematopoiesis (CH) is an inherited disorder of pluripotent hematopoietic stem cells, recognized in dogs and people. In dogs, the condition has an autosomal recessive inheritance pattern and is associated with dilute hair coat color. In dogs, CH (also known as lethal gray collie disease) is characterized by predictable fluctuations in concentrations of blood cells that occur in 14-day cycles. The pattern is cyclic marked neutropenia and in a different phase, cyclic reticulocytosis, monocytosis, and thrombocytosis. Production of key cytokines involved in regulation of hematopoiesis is also cyclic. The specific lesion in CH is believed to involve defective intracellular signaling, but remains to be explained on the molecular level. Neutropenia predisposes affected animals to infection, and many die of infectious causes. Other related clinical manifestations include bleeding tendency, attributable at least in part to defective platelet function, and systemic amyloidosis, which occurs because of cyclic increases in concentration of acute phase proteins during phases of monocytosis.

13.2.1.2

### DISORDERS OF ERYTHROCYTES

This section describes specific erythrocyte disorders and assumes an understanding of the basic mechanisms of anemia, erythrocytosis, and poikilocytosis, discussed previously. Hemorrhage is a common and important cause of anemia in veterinary species, but the list of potential causes of hemorrhage is almost limitless, including all the various forms of trauma and neoplasia. This chapter does not endeavor to cover them, except for commonly recognized disorders of hemostasis, which are discussed in a later section.

13.2.1.2.1

### Immune-Mediated Disorders

13.2.1.2.1.1

#### Immune-mediated hemolytic anemia

Immune-mediated hemolytic anemia (IMHA) is a condition characterized by increased destruction of erythrocytes because of binding of immunoglobulin to cell surface antigens. It is a common, life-threatening condition in dogs and also has been described in horses, cattle, and cats. Although the clinical picture of IMHA is variable, it typically has an acute onset and causes severe anemia. Some studies have shown that certain dog breeds (cocker spaniels and others) are predisposed to develop IMHA, suggesting the possibility of a genetic component, and the disease is more common in young to middle-aged female dogs. In most cases the reactive antibody is IgG, and hemolysis is extravascular (i.e., RBCs with bound antibody are phagocytosed by macrophages, mainly in the spleen). IgM and/or complement proteins may also contribute to IMHA. Complement usually acts as an opsonin (C<sub>3</sub>b) that promotes phagocytosis. However, formation of the complement membrane attack complex and resulting intravascular hemolysis is also a recognized mechanism and more likely to occur with IgM autoantibodies. Most immunoglobulins implicated in IMHA are reactive at body temperature (warm hemagglutinins). A smaller portion, usually IgM, are more reactive at lower temperatures and may lead to a condition known as cold hemagglutinin disease—ischemic necrosis at anatomic extremities (e.g., tips of the ears), where cooling of the circulation causes autoagglutination of erythrocytes and occlusion of the microvasculature. Typically, IMHA targets mature erythrocytes and is accompanied by a marked regenerative response. However, as discussed earlier in the chapter, immune-mediated destruction of immature erythroid cells in the bone marrow may also occur, resulting in nonregenerative anemia (ineffective erythropoiesis).

781

782

In veterinary medicine, IMHA is usually idiopathic (also called primary IMHA or autoimmune hemolytic anemia), and the specific trigger for the autoimmune reaction is not clear. Factors implicated in secondary IMHA include infection, drug administration, vaccination, neoplasia, and bee sting envenomation. Diagnosis of secondary IMHA is most often based on circumstantial evidence and exclusion of other known causes of hemolytic anemia, rather than on controlled experiments proving a direct causal relationship. Infectious agents affecting blood cells are discussed in more detail later. Drugs or chemicals associated with or suspected of causing IMHA in animals include antibiotics (cephalosporins, penicillin, sulfonamides), levamisole, propylthiouracil, and the insecticide pirimicarb. Most drug-induced IMHA is believed to occur because of drug or drug metabolite interacting with the erythrocyte plasma membrane. Other proposed mechanisms include binding of drug-antibody immune complexes to the erythrocyte membrane, or induction of a true autoantibody directed against an erythrocyte antigen. A case of suspected vaccine-associated IMHA has been reported in a cow. Certain vaccines used in cows have been incriminated in the development of a specific form of IMHA in newborn calves—neonatal isoerythrolysis, which is discussed later. Retrospective studies investigating the relationship between vaccination history and development of IMHA in dogs have yielded conflicting results.

Other common clinical findings in patients with IMHA include hyperbilirubinemia, splenomegaly, pyrexia, and inflammatory neutrophilia. These abnormalities vary in magnitude depending on the severity and duration of disease. Dogs with IMHA are also predisposed to develop hemostatic abnormalities (prolonged coagulation times, decreased plasma AT concentration, increased plasma concentration of FDPs/D-dimer, thrombocytopenia, and DIC). The severity of postmortem lesions in dogs with IMHA, including ischemic necrosis within vital organs (liver, kidney, heart, lung) and the spleen as a result of thromboembolic disease or hypoxia has been shown to correlate with the severity of leukocytosis. Intravascular hemolysis (IVH) plays a relatively insignificant role in most cases of IMHA, but evidence of IVH (hemoglobinemia, hemoglobinuria) is noted occasionally, presumably in those cases in which IgM and complement are major mediators of hemolysis.

### 13.2.1.2.1.1.1

#### Neonatal isoerythrolysis.

A form of IMHA whose specific pathogenesis is well understood is neonatal isoerythrolysis (NI), a condition in which a newborn has colostrum-derived maternal antibodies, which react against its own erythrocytes. NI is common in horses (Fig. 13-26) and has been reported in cattle, cats, and some other domestic and wildlife species. In horses, this situation occurs as a result of immunosensitization of the dam from exposure to an incompatible blood type inherited from the stallion (e.g., transplacental exposure to fetal blood during pregnancy or mixing of maternal and fetal blood during parturition). A previously mismatched blood transfusion will produce the same results. Some equine blood groups are more antigenic than others; in particular, types Aa and Qa are very immunogenic in mares. Severely affected foals become lethargic and weak as early as 8 to 10 hours after birth or at any time during the succeeding 4 to 5 days. They have pale, icteric mucous membranes and may have hemoglobinuria. Serum bilirubin concentrations are usually increased, and foals that die during a hemolytic crisis are notably icteric and have splenomegaly. In cattle, NI has been associated with vaccination with whole blood products or products containing erythrocyte membrane fragments. In cats, the recognized form of NI does not depend on prior maternal immunosensitization but on naturally occurring anti-A antibodies in queens with Type B blood. NI has been produced experimentally in dogs, but there are no reports of naturally occurring disease. NI can be prevented by typing the maternal and paternal blood and not allowing neonates from

## Pathologic Basis of Veterinary Disease, 4th Edition

---

incompatible matings access to the mother's colostrum, or by not allowing animals with strongly incompatible blood types to breed.

**Fig. 13-26 Neonatal isoerythrolysis, foal.** Note the enlarged spleen (also liver) and icterus. The newborn foal had colostrum-derived maternal antibodies, which reacted against its own erythrocytes. Macrophages in the splenic red pulp remove erythrocytes whose membranes have bound antibody. (*Courtesy College of Veterinary Medicine, University of Illinois.*)

13.2.1.2.1.2

### Pure red cell aplasia

Pure red cell aplasia (PRCA) is a rare bone marrow disorder characterized by absence of erythropoiesis and severe nonregenerative anemia. Primary and secondary forms of PRCA have been described in dogs and cats. Primary PRCA is apparently caused by immune-mediated destruction of early erythroid progenitor cells, a presumption supported by the response of some patients to immunosuppressive therapy and by the detection of antibodies inhibiting erythroid colony formation in vitro in some dogs. Infection with feline leukemia virus subgroup C is associated with secondary erythroid aplasia in cats, probably because of infection of early stage erythroid precursors. Parvoviral infection has been suggested as a possible cause of secondary PRCA in dogs. Administration of recombinant human erythropoietin (rhEpo) has been identified as a cause of secondary PRCA in dogs, cats, and horses, presumably due to induction of antibodies against rhEpo that cross-react with endogenous erythropoietin. Experimentation with the use of species-specific recombinant erythropoietin has produced mixed results. Dogs treated with recombinant canine Epo have not developed PRCA. However, in experiments reported thus far involving cats treated with recombinant feline Epo, at least some animals have developed PRCA.

782

783

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 13.2.1.2.2 Infectious Disorders

Although various types of infections are associated with anemia of chronic disease, as discussed in the section on mechanisms of nonregenerative anemia, there are also a number of infectious agents that cause anemia directly by targeting erythrocytes. This section outlines important specific protozoal, bacterial, and viral causes of anemia in domestic animals.

#### 13.2.1.2.2.1 Protozoal agents

##### 13.2.1.2.2.1.1 *Babesia* species.

*Babesia* spp. are intraerythrocytic protozoal organisms (piroplasms) spread by arthropods (ticks, biting flies), transplacentally, and by blood transfusions. The apparent higher prevalence of babesiosis in some canine breeds has led to speculation that infection also may be transmitted by dog fighting. *Babesia* spp. cause hemolytic anemia in horses, cattle, dogs, cats, and various nondomesticated animals. *Babesia* organisms are typically classified as large or small form, based on routine light microscopic morphology. Examples of large and small form organisms are shown in [Fig. 13-27](#). *Babesia equi* and *Babesia caballi* infect horses and other equids in tropical and subtropical areas worldwide (*Babesia equi*, which also infects lymphocytes, is not considered a true *Babesia*, but is phylogenetically more closely related to *Theileria* and *Cytauxzoon*). *Babesia bovis* and *Babesia bigemina* (small and large form organisms, respectively) are pathogenic *Babesia* spp. in cattle. These organisms have a worldwide distribution but have been eradicated in North America. Other, less pathogenic *Babesia* spp. may also infect cattle. In dogs, the large form *Babesia canis* and at least three small forms, including *Babesia gibsoni* and other as yet unnamed species, cause hemolytic anemia. *Babesia canis* has three subtypes (*canis*, *rossi*, and *vogeli*). *Babesia canis vogeli*, considered the least pathogenic strain, is the most common one in the United States. In some areas, particularly the southeastern United States, the seroprevalence of *Babesia canis* is high, and many infected dogs are asymptomatic chronic carriers. A number of small form *Babesia* spp. (*Babesia cati*, *Babesia felis*, *Babesia herpailuri*, and *Babesia pantherae*) are reported to cause hemolytic anemia in domestic and wild cats in South America, Africa, and India.

Fig. 13-27 **Babesiosis, canine blood smear.** **A**, Small form of *Babesia* (consistent with *Babesia gibsoni*). **B**, *Babesia canis* organisms infecting erythrocytes. Wright's stain. (**A** and **B** Courtesy Dr. M.M. Fry, College of Veterinary Medicine, University of Tennessee.)

Babesiosis may cause both intravascular and extravascular hemolysis, and is also associated with a wide range of other clinical signs. The wide variety of clinical signs is due to variations in pathogenicity of the organisms and susceptibility of the host. Infection with highly virulent strains may cause severe multisystemic disease. In these cases, massive immunostimulation and cytokine release cause circulatory disturbances, which may result in shock, induction of the systemic inflammatory response, and multiple organ dysfunction syndromes. Mechanisms of hemolysis may include direct damage to the erythrocyte by protozoal proteases, immune-mediated destruction, and oxidative damage. In animals with acute disease, signs often include fever, lethargy, pallor, hemoglobinuria, splenomegaly, and icterus. Animals are often thrombocytopenic, presumably due to

783

784

## Pathologic Basis of Veterinary Disease, 4th Edition

---

immune-mediated destruction of platelets. They also may have lymphadenopathy. Less common signs include edema, ascites, signs of central nervous system dysfunction, renal failure, rhabdomyolysis, stomatitis, and gastroenteritis.

*Babesia* organisms can usually be detected on a routine blood smear in animals with acute disease. Infected erythrocytes may be more prevalent in capillary blood, so blood smears made from samples taken from the pinna of the ear or the nail bed may increase the likelihood of detecting organisms microscopically. Buffy coat smears also have an enriched population of infected RBCs. PCR testing is the most sensitive assay for detecting infection in animals with very low levels of parasitemia. At necropsy, animals dying of the acute disease have notable splenomegaly, jaundice, hemoglobinuria, swollen hemoglobin-stained kidneys, and subepicardial and subendocardial hemorrhages. The cut surface of the enlarged, congested spleen oozes blood. The gallbladder is usually distended with thick bile. A striking feature of *Babesia bovis* infections is congestion of gray matter throughout the brain, which is readily visible compared with the white matter. Parasitized erythrocytes are best visualized on impression smears of the kidney, brain, and skeletal muscle. Microscopic findings in the liver and kidney are typical of a hemolytic crisis and include anemia-induced degeneration and loss of periacinar hepatocytes and cholestasis, and hemoglobinuric nephrosis with degeneration of tubular epithelium. Erythroid hyperplasia is present in the bone marrow. In animals that survive the acute disease, there is hemosiderin accumulation in the liver, kidney, spleen, and bone marrow. In chronic cases, there is hyperplasia of macrophages in the red pulp of the spleen.

### 13.2.1.2.2.1.2

#### Cytauxzoon felis.

*Cytauxzoon felis* is a protozoal organism causing severe, often fatal, disease in cats. Cytauxzoonosis in domestic cats is relatively common in the South Central United States, particularly during summer months. Bobcats (*Lynx rufus*), and perhaps other wild felids, are believed to be the reservoir host. They are usually asymptomatic, with persistent parasitemia and transient schizogony. *Cytauxzoon felis* is transmitted by a tick vector, *Dermacentor variabilis*, which is probably essential for infectivity of the organism. Cytauxzoonosis has a schizogenous phase involving macrophages throughout the body (especially liver, spleen, lung, lymph nodes, and bone marrow) that causes systemic illness, and an erythrocytic phase that causes anemia of variable severity. Schizont-containing macrophages (Fig. 13-28) enlarge and accumulate within the walls of veins, eventually causing occlusion of the vessels. Merozoites are released and enter erythrocytes. Parasitemia develops relatively late in the course of infection. The signet ring-shaped erythrocytic inclusions (piroplasms) of *Cytauxzoon felis* closely resemble small form *Babesia* (Fig. 13-27, A) and some *Theileria* organisms. Affected cats typically become acutely ill with fever, pallor, and icterus and usually die within 2 to 3 days. For many years, cytauxzoonosis was considered to be almost always fatal. However, a recent report, in which numerous cats from a subregion of the endemic area in the United States survived infection with an organism with greater than 99% homology to *Cytauxzoon felis*, suggests the emergence of a less virulent strain. In affected cats, erythrophagocytosis is also often a prominent finding in tissue with the schizogenous phase.

Fig. 13-28 **Cytauxzoonosis, cat.** **A**, Lymph node aspirate. A large macrophage is laden with schizonts of *Cytauxzoon felis*. Wright's stain. **B**, Splenic macrophages are filled with *Cytauxzoon* organisms. H&E stain. (**A** Courtesy Dr. D.F. Edwards, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy Dr. A.R. Doster, University of Nebraska; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

13.2.1.2.2.1.3

*Theileria* species.

*Theileria* spp. are tick-borne protozoal organisms that infect many domestic and wild artiodactyls worldwide. Infection is characterized by intralymphocytic schizonts and pleomorphic intraerythrocytic piroplasms (merozoites and trophozoites). The latter stages closely resemble *Cytauxzoon* and small form *Babesia* spp. Recognized theilerial pathogens in cattle include *Theileria*

784

785

## Pathologic Basis of Veterinary Disease, 4th Edition

---

*parva* (the cause of East Coast fever in Africa), *Theileria annulata* (the cause of tropical theileriosis in the Mediterranean regions, Middle East, and Asia), and *Theileria buffeli*, which has recently been documented as a cause of hemolytic anemia in the United States. Possible mechanisms of anemia in theileriosis include invasion of erythroid precursors by merozoite stages and associated erythroid hypoplasia (as occurs with *Theileria parva* infection), immune-mediated hemolysis, mechanical fragmentation because of vasculitis or microthrombi, enzymatic destruction by proteases, and oxidative damage. Clinical signs in a severely anemic cow infected with *Theileria buffeli* included recumbency, fever, pallor, tachycardia, and lymphadenopathy. Necropsy findings included splenic hemosiderosis, edema of lymph nodes and the subcutis, thoracic and peritoneal effusions, and pneumonia.

13.2.1.2.2.1.4

### *Trypanosoma* species.

Trypanosomes are flagellated protozoa that normally survive and are nonpathogenic in wildlife reservoir hosts. They are transmitted by arthropod vectors. Some *Trypanosoma* spp. are recognized as causing hemolytic anemia in animals in tropical and subtropical regions outside of North America. *Theileria brucei* and *Theileria evansi* affect horses. *Theileria congolense* and *Theileria vivax* affect cattle. *Trypanosoma* spp. that causes anemia in other species includes *Trypanosoma simiae* in pigs and *Trypanosoma brucei* in camels and horses. Trypanosomes also cause nonhemolytic disease (e.g., *Trypanosoma cruzi*, the agent of Chagas' disease, or American trypanosomiasis) in many hosts, and nonpathogenic variants (e.g., *Trypanosoma theileri* in cattle worldwide) are also recognized. Trypanosomal organisms do not infect erythrocytes but rather exist as free trypomastigotes (flagellated forms with a characteristic undulating membrane) in the blood (Fig. 13-29, A) or as amastigotes in tissue. The mechanism of anemia is believed to be immune-mediated. Cattle with acute trypanosomiasis have significant anemia, which initially is regenerative, but less so with time. The extent of parasitemia is readily apparent with *Trypanosoma vivax* and *Trypanosoma theileri* infections because the organisms are present in large numbers in the blood. This is in contrast to *Trypanosoma congolense*, which localizes within the vasculature of the brain and skeletal muscle. Cattle with *Trypanosoma congolense* infections develop chronic debilitating disease; they have scruffy hair coats, appear "potbellied," and have fever, intermittent diarrhea, and exercise intolerance. Mortality is greater with *Trypanosoma vivax* infections, usually because of intercurrent acute infectious diseases, such as salmonellosis. Necropsy findings in cattle with trypanosomiasis include cachexia, generalized edema with increased fluid in body cavities, and generalized lymph node enlargement. Bronchopneumonia, a flabby heart, and serous atrophy of pericardial fat may be present. Liver and kidneys are symmetrically enlarged. Lymph nodes are enlarged up to four times normal size because of lymphoid hyperplasia, and most of the fatty bone marrow is replaced by red hematopoietic tissue. The spleen is enlarged because of lymphoid hyperplasia and is firm when incised.

Fig. 13-29 **Hemotropic parasites, bovine blood smear.** **A**, Trypanosomiasis. Trypanosomes are flagellated protozoa characterized by an undulating membrane, kinetoplast, and nucleus. They may be identified in a wet mount made from the buffy coat portion of the packed cells. **B**, Anaplasmosis, *Anaplasma marginale*. Note the darkly stained organisms, most of which are located on the edges of the erythrocytes. Anaplasmosis causes anemia mainly by immune-mediated extravascular hemolysis. (**A** Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy Dr. J. Simon, College of Veterinary Medicine, University of Illinois.)

## 13.2.1.2.2.2 Bacterial and rickettsial agents

### 13.2.1.2.2.2.1 *Anaplasma* species.

*Anaplasma* spp. are rickettsial organisms that may be transmitted by arthropod vectors (ticks, biting flies) or by blood-contaminated needles. Anaplasmosis is a cause of hemolytic anemia in cattle in tropical and subtropical areas of many parts of the world. *Anaplasma marginale*, considered the more pathogenic species, has a worldwide distribution. *Anaplasma centrale* is found in South America, Africa, and the Middle East. The genus names reflect the typical locations of the organisms when detected on examination of a blood smear, either on the periphery or more centrally within infected erythrocytes. A related species, *Anaplasma ovis*, affects sheep and goats in tropical and subtropical areas worldwide. Wild animals such as deer, elk, and bison may be latently infected and serve as reservoir hosts for *Anaplasma marginale*. *Anaplasma* organisms infect erythrocytes intracellularly.

Anaplasmosis causes anemia mainly by immune-mediated extravascular hemolysis. The severity of disease in infected animals varies with age. Infected calves under 1 year of age rarely develop clinical disease, whereas cattle 3 years of age or older are more likely to develop severe, potentially fatal, illness. The reason for this discrepancy is not clear. In clinically affected animals, common signs include lethargy or recumbency, pallor, and icterus. Animals dying of acute anaplasmosis have blood of low viscosity, pale to icteric tissue, an enlarged turgid spleen, and an icteric liver with a distended gallbladder. In animals with acute disease, it is usually easy to detect *Anaplasma marginale* organisms on routine blood smear evaluation (Fig. 13-29, B). However, in recovering animals, the organisms may be difficult to find. Surviving cattle become chronic carriers (and thus reservoirs for infection of other animals) and develop cyclic parasitemia, which is typically not detectable on blood smears. Splenectomy of carrier animals results in marked parasitemia and acute hemolysis. PCR testing is the most sensitive means of identifying animals with low levels of parasitemia.

### 13.2.1.2.2.2.2 *Clostridium* species.

Certain *Clostridium* spp. may cause potentially fatal hemolytic anemias in animals. The mechanism of hemolysis involves a bacterial toxin (phospholipase C or lecithinase), which enzymatically degrades cell membranes, causing acute intravascular hemolysis. *Clostridium haemolyticum* and *Clostridium novyi* type D cause the disease in cattle known as bacillary hemoglobinuria. (The term *redwater* has also been used for this disease, and for hemolytic anemias in cattle caused by *Babesia* spp.) Similar naturally occurring disease has been reported in sheep and elk. In cattle, the disease is associated with liver fluke (*Fasciola hepatica*) migration in susceptible animals. Ingested clostridial spores may live in Kupffer cells of the liver for a long time without causing disease. However, when migrating flukes cause hepatic necrosis, the resulting anaerobic environment stimulates the clostridial organisms to proliferate and elaborate their hemolytic toxins. Bacillary hemoglobinuria has also been associated with liver biopsy in calves. *Clostridium perfringens* type A causes intravascular hemolytic anemia in lambs and calves—a condition known as yellow lamb disease, yellows, or enterotoxemic jaundice because of the characteristic jaundice. The organism is a normal inhabitant of the gastrointestinal tract in these animals, but may proliferate abnormally in response to some diets. *Clostridium perfringens* has also been associated with intravascular hemolytic anemia in horses with clostridial abscesses and in a ewe with clostridial mastitis.

13.2.1.2.2.2.3

## Hemotropic mycoplasma species.

The term *hemotropic mycoplasmas*, or “hemoplasmas,” encompasses a group of bacteria, formerly known as *Haemobartonella* or *Eperythrozoon* species, that commonly infect RBCs of many domestic, laboratory, and wild animals. Hemotropic mycoplasmas affecting common domestic species are listed in Table 13-4. The organisms are mainly transmitted by arthropods, but some cases of in utero transmission have been reported. Effects of infection vary from subclinical to fatal anemia, depending on the specific organism, dose, and host susceptibility. Anemia occurs mainly because of extravascular hemolysis. Although the pathogenetic mechanisms are not completely understood, an immune-mediated component is highly probable. Hemotropic mycoplasmas (and nonhemotropic mycoplasma ssp.) induce cold agglutinins in infected individuals, although it is not clear whether these particular antibodies are important in the development of hemolytic anemia. Like other mycoplasmas, hemotropic mycoplasmas are small (0.3 to 3 µm in diameter), are gram-negative, and lack a cell wall. They are epicellular parasites, residing in indentations and invaginations of the RBC surface. When detected on routine blood smear evaluation, the organisms are variably shaped (cocci, small rods, or ring forms) and sometimes arranged in short, branching chains (especially *Mycoplasma haemocanis*). The organisms may also be noted extracellularly, in the background of the blood smear, especially if the smear is made after prolonged storage of the blood in an anticoagulant tube. Light and electron photomicrographs of hemotropic mycoplasma organisms are shown in Fig. 13-30.

786

787

Table 13-4 Common Hemotropic Mycoplasmas in Domestic Animals

Host	Organism
Cattle	<i>Mycoplasma wenyonii</i> (formerly <i>Eperythrozoon wenyonii</i> )
Dog	<i>Mycoplasma haemocanis</i> (formerly <i>Haemobartonella canis</i> )
Cat	<i>Mycoplasma haemofelis</i> (formerly <i>Haemobartonella felis</i> large form or Ohio variant)
Cat	Candidatus <i>Mycoplasma haemominutum</i> (formerly <i>Haemobartonella felis</i> small form or California variant)
Pig	<i>Mycoplasma suis</i> (formerly <i>Eperythrozoon suis</i> )
Alpaca	Candidatus <i>Mycoplasma haemolamae</i>

Most hemotropic mycoplasma subspecies are more likely to cause acute illness in individuals that are immunocompromised or have concurrent disease. *Mycoplasma haemofelis* infection is an exception, causing acute hemolytic anemia in immunocompetent cats. The disease in sheep and pigs has a seasonal incidence corresponding to the peak occurrence of biting insects. However, it can also occur at other times of the year as a recrudescence in a carrier animal secondary to another disease. In both sheep and pigs, unexpected death of one or two animals is often followed by anemia in other animals within the herd. *Mycoplasma wenyonii* in cattle is less pathogenic than *Mycoplasma ovis* and *Mycoplasma suis* in sheep and pigs, respectively. Infection with *Mycoplasma wenyonii* appears to be widespread, but it rarely causes disease. Clinical signs in animals with acute disease include lethargy, fever, and pallor. Affected animals usually have mild to moderate hyperbilirubinemia and may be icteric. Animals probably remain chronically infected after recovery, even if treated with appropriate antibiotics. Chronically infected cattle, sheep, and pigs may have decreased production. Chronically infected dogs and cats are typically asymptomatic. In dogs, *Mycoplasma haemocanis* infection is usually subclinical in immunocompetent animals but causes acute hemolytic anemia when infected animals receive a splenectomy. Two forms of hemoplasmas are known to infect cats.

## Pathologic Basis of Veterinary Disease, 4th Edition

As mentioned earlier, *Mycoplasma haemofelis*, the large form variant, causes acute hemolytic anemia in immunocompetent animals. Cats infected with the small form variant, which has the proposed name *Mycoplasma haemominutum*, are typically asymptomatic or have only mild disease. Organisms are often, but not always, detected on routine blood smear examination in acutely ill animals. PCR testing is the most sensitive means of detecting infection in animals with low levels of parasitemia. In animals dying of hemotropic mycoplasma infection, the findings are typical of extravascular hemolysis, with pallor, icterus, and splenomegaly, and distended gallbladder (Fig. 13-31). Microscopic lesions in the spleen include congestion, erythrophagia, macrophage hyperplasia, extramedullary hematopoiesis, and increased numbers of plasma cells. Bone marrow has varying degrees of erythroid hyperplasia, depending on the duration of hemolysis.

**Fig. 13-30 Hemotropic mycoplasmosis. A,** Blood smear from a splenectomized pig infected with *Mycoplasma suis* (formerly *Eperythrozoon suis*). Zachary, College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

13.2.1.2.2.2.4

*Leptospira* species.

Leptospirosis is recognized as a cause of hemolytic anemia in calves, lambs, pigs, and black rhinoceros. Specific leptospiral organisms associated with hemolytic disease include *Leptospira interrogans* serovars *pomona* and *ictohaemorrhagica*. Proposed mechanisms of disease include immune-mediated (IgM cold agglutinin) extravascular hemolysis and enzymatic (phospholipase produced by the organism) intravascular hemolysis.

*Leptospira* organisms are ubiquitous in the environment. Infection occurs percutaneously and via mucosal surfaces and is followed by leptospiremia; organisms then localize preferentially in certain tissues (e.g., kidney, liver, and pregnant uterus). Leptospirosis can also cause many disease manifestations besides hemolysis (e.g., renal failure, liver failure, abortion, and other conditions) that are not discussed here.

787

788

Fig. 13-31 ***Mycoplasma haemofelis*, cat.** Note the splenomegaly, hepatomegaly, and icterus caused by infection of erythrocytes with this hemotropic parasite. Splenomegaly and icterus are the result of increased destruction (extravascular hemolysis) of infected erythrocytes. (Courtesy College of Veterinary Medicine, University of Illinois.)

In addition to anemia, common findings in animals with leptospirosis-induced hemolysis include hemoglobinuria and icterus. On necropsy, renal tubular necrosis, which occurs in part because of hemoglobinuria (hemoglobinuric nephrosis), may also be present.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

13.2.1.2.2.3

### Viral agents

13.2.1.2.2.3.1

#### Equine infectious anemia virus.

Equine infectious anemia virus (EIAV) is a lentivirus that infects cells of the mononuclear phagocyte system in horses (also ponies, donkeys, and mules) throughout the world. Natural transmission is by arthropods, and the virus can also be transmitted transplacentally. Disease occurs in both an acute, potentially fatal form after initial infection, as well as a chronic intermittent form associated with recurrent viremia. Recurrent episodes happen mostly in the first year after infection, and tend to decrease in frequency and severity with time. Infection is lifelong and animals may become asymptomatic carriers. Viral antigen is found mainly within liver, spleen, and serum of infected animals, and also in bone marrow, lymph nodes, thymus, circulating mononuclear cells, and other tissues. EIAV causes anemia by both immune-mediated hemolysis and decreased erythropoiesis. Hemolysis is typically extravascular but may have an intravascular component during the acute phase. Decreased erythropoiesis may result from direct suppression of early-stage erythroid cells by the virus, as well as anemia of inflammation. Thrombocytopenia, likely due to secondary immune-mediated destruction, is also a classic feature of acute EIAV infection and recurring febrile episodes. Clinical findings associated with viremic episodes include fever, depression, icterus, petechial hemorrhages, lymph node enlargement, and dependent edema. EIA infection is diagnosed on the basis of the Coggins test, an agarose gel immunodiffusion test for the presence of the antibody against the virus.

Animals dying during hemolytic crises have icterus, anemia, and widespread hemorrhages. The spleen and liver are enlarged, dark and turgid, and they and other organs have superficial subcapsular hemorrhages. Petechiae are evident beneath the renal capsule and throughout the cortex and medulla. The bone marrow is dark red as a result of replacement of fat by hematopoietic tissue; the extent of replacement is an indication of the duration of the anemia. The severity of microscopic lesions is dependent on the chronicity of the disease, and they are most significant in the spleen, liver, and bone marrow. As would be anticipated, microscopic findings of the spleen are predominantly influenced by the number and activity of macrophages, which is a reflection of the duration of the disease and the frequency of hemolytic episodes. Hemosiderin-laden macrophages persist for months to years; therefore, large numbers are consistent with chronicity. Kupffer cell hyperplasia with hemosiderin stores and periportal infiltrates of lymphocytes are the most significant changes in the liver. Bone marrow histologic findings vary depending on the duration of the disease. In most animals, the marrow is cellular because of the replacement of fat by intense, orderly erythropoiesis. Granulocytes are relatively less numerous and plasma cells are increased. As in the spleen, hemosiderin-laden macrophages are present in large numbers in chronic cases. In more chronic cases, emaciated animals have serous atrophy of fat.

13.2.1.2.2.3.2

#### Feline leukemia virus.

Feline leukemia virus (FeLV) is an oncogenic, immunosuppressive lentivirus associated with hematologic abnormalities of widely varying type and severity, including anemia in most infected cats. Manifestations of disease due to FeLV infection vary depending on dose, viral genetics, and host factors, but normal hematopoiesis is probably suppressed to some degree in all cases. The virus infects hematopoietic precursor cells soon after the animal is exposed and continues to replicate in hematopoietic and lymphatic tissue of animals that remain persistently viremic. Persistently viremic

## Pathologic Basis of Veterinary Disease, 4th Edition

cats are immunosuppressed and are prone to developing other diseases, including infectious diseases, bone marrow disorders, and lymphoma (lymphosarcoma).

788

FeLV-induced anemia is usually nonregenerative, presumably due to direct effects of the virus on infected erythroid cells. However, macrocytosis and metarubricytosis (the presence of nucleated RBC precursors in circulation) are often noted in the absence of significant reticulocytosis—findings consistent with dyserythropoiesis, although the exact mechanism is not clear. Bone marrow of cats with FeLV-induced anemia often has evidence of arrested or disordered maturation of hematopoietic precursors. The relatively uncommon subgroup C viruses are associated with erythroid aplasia, probably because of infection of early stage erythroid precursors. Regenerative anemia may also occur with FeLV infection, often because of coinfection with *Mycoplasma haemofelis*.

789

13.2.1.2.2.3.3

### Feline immunodeficiency virus.

Feline immunodeficiency virus (FIV), another feline lentivirus, is associated with anemia in a minority of infected cats. Immunosuppressive effects of FIV from thymic depletion are discussed elsewhere. It is generally accepted that anemia does not result directly from FIV infection, but instead develops because of concurrent disease, such as co-infection with FeLV or hemotropic mycoplasma, other infection, or malignancy. The severity and type of anemia in FIV-infected cats depends on the other specific disease processes involved.

13.2.1.2.3

### Acquired and Inherited Metabolic Disorders

This section discusses specific acquired and inherited metabolic disorders that cause anemia or impaired hemoglobin function.

13.2.1.2.3.1

### Oxidative agents

Rather than presenting an exhaustive list, this section describes some of the more commonly recognized oxidants that cause hemolytic anemia or impaired hemoglobin function in common domestic species. Oxidative insult may result in extravascular hemolysis because of phagocytosis of damaged erythrocytes by splenic macrophages, or in intravascular hemolysis if the damage is severe enough. In horses, red maple (*Acer rubrum*) toxicity is a well-characterized, potentially fatal cause of acute intravascular hemolytic anemia and methemoglobinemia. Ingestion of sufficient amounts of wilted or dried leaves or bark causes Heinz body formation, eccentrocytosis, severe intravascular hemolysis, and methemoglobinemia. Common postmortem findings include notable icterus; splenic hemosiderosis; splenomegaly; brown discoloration and swollen liver; and swollen kidneys, which can be dark red to blue-black. Histologically the kidneys have characteristic red-brown tubular casts (hemoglobinuric nephrosis).

Phenothiazine can cause Heinz body formation in horses. In ruminants, *Brassica* spp. and rye grass are associated with Heinz body formation, and nitrite toxicity causes methemoglobinemia.

Copper toxicity is a well-known cause of acute intravascular hemolytic anemia in sheep, and may also occur in goats and calves. The condition occurs in animals that have accumulated large amounts of copper in the liver. The copper is released under conditions of stress (e.g., shipping, starvation) and is believed to cause hemolysis as a result of direct interaction with membrane proteins, lipid peroxidation,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

formation of reactive oxygen species, and enzyme inhibition. Affected animals are often markedly icteric, and hemoglobinuric nephrosis is a classic postmortem lesion.

Onions and garlic are most commonly recognized as a cause of Heinz body hemolytic anemia in dogs and cats but can cause oxidative damage to erythrocytes in other domestic animals, including horses and cattle. Other causes of Heinz bodies in dogs include acetaminophen, benzocaine, naphthalene, phenylhydrazine, vitamins K<sub>1</sub> and K<sub>3</sub>, and zinc. Other causes of Heinz bodies in cats include acetaminophen, benzocaine, methionine, naphthalene, propofol, and propylene glycol.

13.2.1.2.3.2

### Nutritional deficiencies

Severe malnutrition is probably a cause of nonregenerative anemia in all species due to combined deficiencies of molecular building blocks, energy, and essential cofactors. By far the most commonly recognized specific deficiency that results in anemia is iron deficiency. Iron deficiency is usually not a primary nutritional deficiency but rather occurs secondary to depletion of iron stores via chronic hemorrhage. The most common route of loss is through the gastrointestinal tract (e.g., due to neoplasia [especially gastrointestinal carcinoma or lymphoma] in older animals, or hookworm infection in puppies). Chronic hemorrhage may also be due to many other causes, including marked ectoparasitism (e.g., pediculosis in cattle, and massive flea burden in kittens and puppies), neoplasia in locations other than the GI tract, and bleeding diatheses. Rapidly growing nursing animals may be iron-deficient when compared with adults because milk is an iron-poor diet. In most cases, this is of little clinical significance (and in fact is normal). An important exception is piglets with no access to iron, which may cause anemia, failure to thrive, and increased mortality. Neonatal piglets are routinely given parenteral iron (intramuscular injection of iron dextran) for this reason.

Other specific nutritional deficiencies causing anemia in animals are uncommon or rare. Copper deficiency can cause iron deficiency in ruminants, and may occur because of copper-deficient forage or impaired usage of copper by high dietary molybdenum or sulfate. It is believed that copper deficiency impairs production of ceruloplasmin, a copper-containing enzyme involved in gastrointestinal iron absorption. Copper deficiency anemia, like iron deficiency anemia, is typically microcytic and hypochromic. Cobalamin (vitamin B<sub>12</sub>) and folate deficiencies are recognized as causes of anemia in human beings but are rare in animals.

789

790

13.2.1.2.3.3

### Hypophosphatemic hemolytic anemia

Marked hypophosphatemia is recognized as a cause of intravascular hemolytic anemia in postparturient dairy cows. Hypophosphatemia develops in these animals because of increased loss of phosphorus in their milk. Biochemical studies suggest that the mechanism of hemolysis involves decreased erythrocyte production of ATP, which may lead to compromised membrane and cytoskeletal integrity. An accompanying decrease in reducing capacity and increase in methemoglobin concentration have also been noted in experimental studies of hypophosphatemic hemolytic anemia in dairy cattle, suggesting that oxidative mechanisms may also contribute to anemia. Affected cows are anemic and hemoglobinuric. Gross postmortem findings include pallor, decreased viscosity of the blood, and discolored pale yellow and swollen liver and kidney. Renal tubular necrosis and hemoglobin pigment within the tubules is evident microscopically. Hemolysis has also been reported in association with hypophosphatemia in dogs and cats.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

13.2.1.2.3.4

### Water intoxication

Calves with sporadic access to water will sometimes drink excessively when water is available, to the point where their plasma becomes hypotonic and osmotic intravascular hemolysis occurs. Hemoglobinuria is commonly observed in affected animals. The condition is rarely fatal.

13.2.1.2.3.5

### Enzyme deficiencies

13.2.1.2.3.5.1

#### Erythropoietic porphyrias.

Porphyrias are inherited defects of enzymes involved in the synthesis of porphyrins, precursors of hemoglobin, and other heme proteins. Porphyrias result in accumulation of toxic porphyrin compounds. Congenital erythropoietic porphyria, transmitted as an autosomal recessive trait, occurs in Holstein and shorthorn cattle and is characterized by red-brown discoloration of teeth, bones, and urine caused by accumulation of porphyrins (see [Fig. 1-74](#)). Because of the circulation of the photodynamic porphyrins in blood, these animals have lesions of photosensitization of the nonpigmented skin and hemolytic anemia. All affected tissues, including erythrocytes, exhibit fluorescence with ultraviolet light. The premature destruction of developing and mature erythrocytes is caused by the accumulation within these cells of excess porphyrins. Bovine erythropoietic protoporphyria is an inherited disorder of heme synthetase, a terminal enzyme of the heme synthetic pathway, resulting in the accumulation of protoporphyrins in tissues and erythrocytes. It is inherited as an autosomal recessive trait and is confined to Limousin or Limousin-cross cattle. Photosensitivity is the only clinical manifestation of the disease; there is no anemia and no discoloration of teeth and bone. A congenital porphyria described in Siamese and domestic short-haired cats resembles congenital erythropoietic porphyria in cattle. These cats have brown teeth, photosensitization, and hemolytic anemia.

13.2.1.2.3.5.2

#### Pyruvate kinase deficiency.

Pyruvate kinase (PK) deficiency is an inherited autosomal recessive condition in numerous dog breeds (most commonly in basenjis) and fewer cat breeds (Abyssinian, Somali, domestic shorthair). The glycolytic isoenzyme that is deficient in erythrocytes of affected animals normally catalyzes the last ATP-generating reaction in glycolysis. Thus in PK-deficient individuals there is decreased production of ATP, which results in loss of normal membrane function and decreased erythrocyte life span. The disease is characterized by moderate to severe extravascular hemolytic anemia that is strongly regenerative. In dogs, PK deficiency typically also involves progressive myelofibrosis, osteosclerosis, and hemosiderosis. Dogs with PK deficiency usually die from complications of the disease by 4 years of age. PCR tests to detect carrier and affected dogs are available for basenjis and West Highland white terriers (and probably Cairn terriers). In cats, PK deficiency is not associated with osteosclerosis, and the prognosis is more favorable.

13.2.1.2.3.5.3

#### Phosphofructokinase deficiency.

Inherited autosomal recessive deficiency of another erythrocyte glycolytic enzyme, phosphofructokinase (PFK), is described in English springer spaniel and American cocker spaniel dogs. The enzyme is also deficient in muscle tissue of affected dogs. Erythrocytes in PFK-deficient

## Pathologic Basis of Veterinary Disease, 4th Edition

dogs have decreased ATP and 2,3-diphosphoglycerate production, and increased fragility under alkaline conditions. The disease is characterized by chronic, extravascular hemolysis with marked reticulocytosis. The marked regenerative response may compensate for the ongoing hemolysis, and affected animals therefore are not necessarily anemic. However, acute intravascular hemolytic episodes may occur with hyperventilation and resulting alkalemia. There are three genes encoding PFK enzymes, designated M in muscle and erythrocytes, L in liver, and P in platelets. A point mutation in the gene coding for the M enzyme results in an unstable, truncated molecule. In English springer spaniels and related breeds, affected and carrier animals can be detected using PCR testing.

13.2.1.2.3.5.4

### Other inherited erythrocyte disorders.

Sporadic cases of other inherited deficiencies of enzymes, or other components of key erythrocyte metabolic pathways, have been reported. Deficiency of cytochrome-b<sub>5</sub> reductase

790

(NADH-methemoglobin reductase), the enzyme that catalyzes the reduction of methemoglobin (Fe<sup>3+</sup>) to hemoglobin (Fe<sup>2+</sup>), has been recognized in a number of dogs and in a cat. Affected animals are not anemic, usually lack clinical signs of disease, and have normal life expectancies. Deficiency of the glycolytic enzyme glucose-6-phosphate dehydrogenase (G6PD), a common X-linked disease in people, has been reported in an American saddle bred colt with eccentrocytosis and persistent hemolytic anemia, and in a partially deficient male dog without anemia or clinical signs. Deficiency of erythrocyte flavin adenine dinucleotide (FAD) due to abnormal erythrocyte riboflavin metabolism was recently reported in a Spanish mustang mare with methemoglobinemia and eccentrocytosis.

791

Japanese black cattle lacking band 3, an integral membrane protein that connects to the cytoskeleton, have moderate hemolytic anemia and retarded growth. A heterogeneous group of conditions, known as hereditary stomatocytosis because of the characteristic slit-shaped area of central pallor in RBCs on stained blood smears, has been described in several dog breeds. The clinical manifestations vary in affected animals, and the specific underlying defects have not been identified. In all cases, however, erythrocytes have increased osmotic fragility and decreased survival. A condition characterized by increased erythrocyte osmotic fragility has been described in Abyssinian and Somali cats, although the specific defect has not been identified. Affected cats have chronic intermittent severe hemolytic anemia and often have other lesions secondary to hemolytic anemia (e.g., splenomegaly and hyperbilirubinemia). Other rare inherited or presumably inherited disorders of erythrocytes have also been described in animals.

13.2.1.3

### DISORDERS OF GRANULOCYTES AND MONOCYTES/MACROPHAGES

13.2.1.3.1

#### Disorders of Granulocytes

13.2.1.3.1.1

#### Granulocytic ehrlichiosis

Ehrlichiae are small, pleomorphic, gram-negative, obligate intracellular bacteria that are transmitted by tick vectors. Some *Ehrlichia* spp. have a tropism for granulocytes, and morulae are sometimes found within the cytoplasm of neutrophils of affected animals (Fig. 13-32). Animals with granulocytic ehrlichiosis may be neutropenic, but the specific mechanism of neutropenia is not clear. Neutropenia is not a consistent finding in granulocytic ehrlichiosis, and clinical manifestations of infection are usually referable to other cell types (e.g., thrombocytopenia) or body systems (e.g., polyarthritis). Molecular analysis has shown that *Ehrlichia equi*, the agent of human granulocytic ehrlichiosis, and *Ehrlichia*

## Pathologic Basis of Veterinary Disease, 4th Edition

*phagocytophila* are genetically indistinguishable. All are now designated as *Anaplasma phagocytophila*. Granulocytic ehrlichiosis occurs naturally in horses (*Anaplasma phagocytophila*), dogs (*Anaplasma phagocytophila* and *Ehrlichia ewingii*), and cats (*Anaplasma phagocytophila*).

Fig. 13-32 **Granulocytic ehrlichiosis, *Anaplasma phagocytophila*, canine blood smear.** The top neutrophil contains an inclusion consistent with an *Anaplasma phagocytophila* morula. Wright's stain. (Courtesy Dr. M.M. Fry, College of Veterinary Medicine, University of Tennessee.)

13.2.1.3.1.2

### Leukocyte adhesion deficiency

Leukocyte adhesion deficiency (LAD) is an inherited fatal autosomal recessive condition characterized by deficiency of the common  $\beta_2$  chain (a molecule also known as CD18) of leukocyte integrins.

Without normal expression of this adhesion molecule, leukocytes have severely impaired ability to migrate from the blood stream into tissues. As a result, animals with LAD are highly susceptible to infections, and usually die at a young age. Infected foci are nonsuppurative because of the absence of infiltrating leukocytes. LAD is also characterized by very high concentrations of neutrophils in the blood. LAD has been recognized in Holstein cattle (known as bovine LAD, or BLAD) and Irish setter dogs.

#### Pelger-Huët anomaly

Pelger-Huët anomaly (PHA) is a condition characterized by lack of normal segmentation of the nuclei of mature granulocytes. This condition results in morphologic changes in granulocytes that are similar to those of granulocytes occurring in an inflammatory left shift; however, in the absence of any other disease process, animals with PHA should not have clinical signs or other laboratory findings indicative of inflammation. PHA cells can be distinguished from immature forms of otherwise normal granulocytes on the basis of their mature chromatin pattern (Fig. 13-33). PHA has been described in dogs, cats, and rabbits, as well as in human beings. Prevalence is higher in certain dog breeds. In

791

792

## Pathologic Basis of Veterinary Disease, 4th Edition

Australian shepherds, the mode of inheritance is autosomal dominant with incomplete penetrance. Most cases of PHA are the heterozygous form and probably of no clinical significance. In these cases, the shape of most granulocyte nuclei resembles those of band and metamyelocyte forms. A rare homozygous form of PHA has also been reported in rabbits and cats. It is associated with accompanying skeletal abnormalities and stillbirths or early mortality in these species (there are also rare reports of homozygous PHA in human beings, without associated skeletal abnormalities or shortened life span). In homozygous PHA cells, granulocyte nuclei are round or oval. An acquired, reversible condition mimicking PHA, known as pseudo-Pelger-Huët anomaly, is occasionally noted in animals with infectious disease, neoplasia, or in connection with drug administration.

**Fig. 13-33 Pelger-Huët anomaly, feline blood smear.** Eosinophil (**A**) and neutrophil (**B**) have hyposegmented nuclei with mature, condensed chromatin. Wright's stain. (**A and B** Courtesy Dr. M.M. Fry, College of Veterinary Medicine, University of Tennessee.)

13.2.1.3.1.3

### Chédiak-Higashi syndrome

Chédiak-Higashi syndrome (CHS) is a rare autosomal recessive condition characterized by recurrent pyogenic infections, bleeding tendencies, ocular and cutaneous hypopigmentation, and prominent cytoplasmic inclusions in blood cells. CHS has been described in domestic (several breeds of cattle, Persian cats), wild (blue and silver foxes, Aleutian mink, an albino killer whale), and laboratory (beige mutant mice and rats) animals, as well as people. The mutated gene encodes a protein called beige or LYST (for lysosome trafficking regulator), the specific functions of which are still being investigated. Individuals with CHS have severely impaired cellular innate immunity because of neutropenia, impaired chemotaxis, and impaired killing by granulocytes and cytotoxic lymphocytes.

### 13.2.1.3.2 Disorders of Monocytes/Macrophages

#### 13.2.1.3.2.1 Monocytic ehrlichiosis

Some ehrlichiae have a tropism for mononuclear cells, but clinical manifestations are usually referable to other cell types or body systems. Ehrlichial morulae may be found in mononuclear cells of infected animals on routine examination of blood smears, and examination of buffy coat smears increases the probability of detecting the organism. In horses, *Ehrlichia risticii*—the agent of Potomac horse fever (also known as equine monocytic ehrlichiosis)—infects monocytes and enterocytes and is primarily a diarrheal disease (see [Chapter 7](#)). In dogs, *Ehrlichia canis*, the agent of canine monocytic ehrlichiosis, infects mononuclear cells. Infection with *Ehrlichia chaffeensis*, the agent of human monocytic ehrlichiosis, has also been reported in dogs. Canine monocytic ehrlichiosis has acute and chronic forms. Acutely ill animals typically have a fever, lymph node enlargement, and splenomegaly.

Thrombocytopenia and nonregenerative anemia are common findings. Untreated dogs recovering from acute disease develop a subclinical phase and may have persistent mild thrombocytopenia. A subset of these dogs develop chronic disease that may be debilitating and in some cases life threatening. Some studies indicate that German shepherd dogs with ehrlichiosis are predisposed to have particularly severe clinical disease. Severe cases are characterized by weight loss, lymph node enlargement, pyrexia, thrombocytopenia, and nonregenerative anemia. Thrombocytopenic animals may have severe bleeding tendencies. Some dogs with chronic disease develop pancytopenia. Necropsy findings vary with the stage of the disease. In the acute disease, there are widespread petechiae and ecchymoses, with splenomegaly and lymphadenomegaly. Chronically infected dogs are emaciated. The bone marrow is hyperplastic and red in the acute disease, but becomes hypoplastic and pale in animals with

792

pancytopenia. Histologic findings include generalized perivascular plasma cell infiltration, which is most pronounced in animals with chronic disease. Multifocal, nonsuppurative meningoencephalitis, interstitial pneumonia, and glomerulonephritis are present in most dogs with the disease. *Ehrlichia* organisms are difficult to detect histologically; examination of Wright-Giemsa–stained impression smears of lung, liver, lymph nodes, and spleen is a more effective method for detecting the morulae in macrophages. Ehrlichiosis is often diagnosed on the basis of serologic testing, but PCR testing is more sensitive.

793

#### 13.2.1.3.2.2 Hemophagocytic syndrome

Hemophagocytic syndrome is a term used to describe proliferation of nonneoplastic (i.e., polyclonal), well-differentiated but highly erythrophagic macrophages. The condition is rare but has been recognized in dogs and cats. Unlike histiocytic sarcoma, which in some forms also consists of highly erythrophagic macrophages, hemophagocytic syndrome is a secondary condition, occurring as a sequela of neoplasia, infection, or other underlying diseases. The macrophage proliferation and hyperactivation is a response to increased production of stimulatory cytokines occurring as part of the primary disease process. Macrophages are found in high numbers in the bone marrow and commonly in other tissues, including lymph nodes, spleen, and liver. Affected animals usually have cytopenias of two or more cell lines. Bone marrow findings reported in animals with hemophagocytic syndrome vary widely, ranging from hypoplasia to hyperplasia of cell lines with peripheral cytopenias, and may also include detection of macrophages containing phagocytosed hematopoietic precursor cells in addition to mature erythrocytes.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 13.2.1.4 DISORDERS OF PLATELETS

#### 13.2.1.4.1 Immune-Mediated Disorders

##### 13.2.1.4.1.1 Immune-mediated thrombocytopenia (IMT)

Immune-mediated thrombocytopenia (IMT) is a condition characterized by immune-mediated destruction of platelets. There are numerous similarities between IMT and IMHA. IMT is a fairly common condition in dogs (it has also been described in horses and cats). It is more common in middle-aged animals, females, and perhaps some breeds of dogs. The disease is usually idiopathic and typically results in severe thrombocytopenia (often  $<10,000$  platelets/ $\mu\text{L}$ ), although less severe forms of the disease also occur. Affected animals have varying degrees of clinical bleeding tendencies. IMT also sometimes occurs together with IMHA, a condition known as Evans syndrome.

Underlying conditions associated with secondary IMT include infection (e.g., EIAV and ehrlichiosis), drug administration, neoplasia, and other immune-mediated diseases. Many types of infectious agents (viral, bacterial, fungal, protozoal) have been associated with IMT, some of which may also cause thrombocytopenia by other mechanisms. Ehrlichiosis, for example, has been shown to elicit production of antibodies that are cross-reactive with platelet antigens in human beings. Drugs suspected of causing IMT in animals include cephalosporins and sulfonamides.

##### 13.2.1.4.1.2 Neonatal alloimmune thrombocytopenia

A form of immune-mediated thrombocytopenia, known as neonatal alloimmune thrombocytopenia, is recognized in neonatal pigs and foals. The pathogenesis of this disease is virtually identical to that of neonatal isoerythrolysis as a cause of anemia: A neonate inheriting paternal platelet antigens absorbs maternal antibodies against these antigens through the colostrum. In principle, a similar situation may occur following platelet-incompatible transfusion of blood or blood products containing platelets.

#### 13.2.1.4.2 Infectious Disorders

This section focuses on infectious agents that specifically affect platelets or platelet precursors. Many other infections may affect platelets indirectly (e.g., via immune-mediated mechanisms).

##### 13.2.1.4.2.1 *Anaplasma platys*

*Anaplasma platys* (known until recently as *Ehrlichia platys*) is a rickettsial organism that infects canine platelets, causing recurrent marked thrombocytopenia (the disease is also known as infectious canine cyclic thrombocytopenia). The disease is tick-borne and has been recognized worldwide. Evidence of megakaryocytic hyperplasia and organism-associated antigen within macrophages indicate that thrombocytopenia likely results from increased platelet destruction. Infection is generally considered to be asymptomatic, and morulae within platelets may be detected on blood smears incidentally, but there are rare reports describing more severe clinical signs in infected animals.

13.2.1.4.2.2

### Bovine viral diarrhea virus

Thrombocytopenia, often severe, has been reported in association with acute bovine viral diarrhea virus (BVDV) infection in calves and adult cattle. Infection with type II BVDV has been specifically associated with a thrombocytopenic hemorrhagic syndrome. Calves infected with type II BVDV have also been shown to have impaired platelet function. Investigations of the mechanism of BVDV-induced thrombocytopenia have resulted in varying, sometimes conflicting, conclusions. More than one study has shown viral antigen associated both with bone marrow megakaryocytes and with circulating platelets. Evidence of impaired thrombopoiesis (megakaryocyte necrosis, megakaryocyte pyknosis, and degeneration) and increased thrombopoiesis (megakaryocytic hyperplasia, increased numbers of immature megakaryocytes) in the bone marrow has been reported in type II BVDV-infected animals, including concurrent megakaryocyte necrosis and hyperplasia in some experimental subjects. To our knowledge, antibody-mediated destruction of platelets has not been shown.

793

794

13.2.1.4.2.3

### Feline leukemia virus

As discussed earlier in the section on disorders of erythrocytes, FeLV infects hematopoietic cells and can produce a wide array of hematologic and other disease manifestations. FeLV may be detected in megakaryocytes and platelets in infected cats, and may result in platelet abnormalities, including thrombocytopenia, thrombocytosis, increased platelet size, and decreased function. Proposed mechanisms of FeLV-induced thrombocytopenia include direct cytopathic effects, myelophthisis, and immune-mediated destruction. Platelet life span and function have been shown to be decreased in FeLV-positive cats.

13.2.1.4.3

### Inherited Platelet Function Disorders

Defective platelet function may cause bleeding in individuals that lack other hemostatic abnormalities. Platelet function disorders, also known as thrombopathies or thrombopathias, may be primary or secondary. [Box 13-9](#) shows underlying conditions associated with secondary thrombopathies. Examples of well-characterized primary thrombopathies recognized in common domestic animals are discussed in more detail next. Sporadic reports of other thrombopathies in veterinary species have also been reported.

13.2.1.4.3.1

#### Box 13-9 Conditions Associated with Secondary Thrombopathy

- Hyperglobulinemia (as in monoclonal gammopathy due to multiple myeloma, or polyclonal gammopathy due to persistent antigenic stimulation)
- Increased concentrations of fibrinolytic products (because of increased production, as in DIC, or impaired clearance, as in liver insufficiency)
- Uremia
- Immune-mediated thrombocytopenia (antibodies bound to platelets may cause impaired function as well as increased destruction)
- Colloidal plasma expanders (e.g., Hetastarch)

## Pathologic Basis of Veterinary Disease, 4th Edition

- Infection (BVDV, FeLV)
- NSAIDs—irreversible (aspirin) or reversible inhibition of cyclooxygenase

*BVDV*, Bovine viral diarrhea virus; *DIC*, disseminated intravascular coagulation; *FeLV*, feline leukemia virus; *NSAIDs*, nonsteroidal antiinflammatory drugs.

13.2.1.4.3.2

### Chédiak-Higashi syndrome

One of the classic features of CHS (discussed earlier in the section on disorders of granulocytes) is a bleeding tendency due to platelet dysfunction. Platelets in individuals with CHS lack the dense granules that normally contain key bioactive molecules involved in hemostasis, including platelet agonists, such as ADP and serotonin, and platelet aggregation in vitro in response to collagen, in particular, is severely impaired.

13.2.1.4.3.3

### Simmental hereditary thrombopathy

An inherited platelet function defect resulting in a severe bleeding tendency has been reported in Simmental cattle. The mode of inheritance is apparently not simple mendelian recessive, and the condition may involve mutations of more than one gene. The condition is characterized clinically by spontaneous epistaxis, hematuria, and excessive bleeding in response to minor surgical (e.g., castration) and other (e.g., ear tagging or tattooing) procedures. Platelet aggregation in vitro in response to a number of agonists is markedly impaired. The specific defect has not been identified on the molecular level.

13.2.1.4.3.4

### Glanzmann thrombasthenia

Glanzmann thrombasthenia (GT) is an inherited platelet function defect caused by defective expression of the integrin  $\alpha\text{IIb}\beta_3$  (also known as GPIIb-IIIa). The  $\alpha\text{IIb}\beta_3$  molecule has a number of functions, but is best known as a fibrinogen receptor that is essential for normal platelet aggregation. Bleeding tendencies vary widely between affected individuals, and bleeding tends to occur mainly on mucosal surfaces. The condition is characterized by an in vitro lack of response to all platelet agonists and severely impaired clot retraction. GT has been recognized in Great Pyrenees and otterhound dogs and in a quarter horse and a thoroughbred horse; a clinically similar condition that does not fulfill molecular criteria of GT has been described in basset hound dogs.

13.2.1.4.3.5

### Scott-like syndrome

An inherited thrombopathy resembling Scott syndrome in human beings, in which platelets lack normal procoagulant activity, has been recognized in a family of German shepherd dogs. Affected dogs have a mild to moderate clinical bleeding tendency characterized by epistaxis, hyphema, intramuscular hematoma formation, and increased hemorrhage associated with surgery. The specific defect in these dogs has not been identified on the molecular level, but involves impaired expression of phosphatidylserine on the platelet surface.

794

795

13.2.1.4.3.6

### von Willebrand disease

von Willebrand disease (vWD) actually refers to a group of inherited conditions characterized by a quantitative or qualitative deficiency of von Willebrand factor (vWF), a soluble multimeric glycoprotein that circulates as a complex with and stabilizes coagulation factor VIII, and mediates binding of platelets to subendothelial collagen (see [Fig. 2-18](#)). Although not technically a platelet disorder, vWD is often classified as such because it results in a loss of normal platelet function. vWD is the most common canine hereditary bleeding disorder and has also been described in many other domestic species. Different types of vWD vary in terms of mode of inheritance and severity of clinical disease. Type I vWD is characterized by low plasma vWF concentration but normal multimer proportions and a mild to moderate clinical bleeding tendency; it has been reported in many dog breeds. Type II vWD is characterized by low vWF concentration, absence of large multimers, and a moderate to severe bleeding tendency; it has been reported in German shorthaired pointer and German wirehaired pointer dogs. Type III vWD is characterized by absence of vWF and a severe bleeding tendency; familial and sporadic cases have been reported in numerous dog breeds.

13.2.1.4.4

### Breed-Related Platelet Abnormalities

Cavalier King Charles spaniels often have a lower than normal concentration of platelets, many of which are abnormally large (a condition known as macrothrombocytopenia). This is likely an autosomal recessive trait. In general, affected dogs are asymptomatic. Cavalier King Charles spaniels have been shown to have abnormal platelet aggregation in vitro in some studies, although the clinical significance of these findings, including a possible causal relationship between platelet abnormalities and mitral valve disease in this breed, is not clear.

Greyhounds tend to have lower concentrations of circulating platelets than other dog breeds (and lower concentrations of erythrocytes and higher MCV and PCV), although this is not of any known clinical significance.

13.2.1.5

### DISORDERS OF LYMPHOCYTES

Disorders of lymphocytes are discussed in the sections on the lymphatic system and in the next section on hematopoietic neoplasia (also see [Chapter 6](#)).

13.2.1.6

### HEMATOPOIETIC NEOPLASIA

The term *hematopoietic neoplasia* encompasses a large, diverse group of clonal proliferative disorders of hematopoietic cell types. This section is intended to help the student understand the basic biology (cell type, anatomic distribution, and biologic behavior) and diagnosis of hematopoietic neoplasia in veterinary medicine, with an emphasis on those forms that predominantly affect bone marrow, blood, and lymphoid tissue. Tumors of hematopoietic origin that predominantly affect other tissue, such as skin, will also be mentioned. Before listing specific diseases, it is worthwhile to consider the basic classification of hematopoietic neoplasia and mention some of the emerging diagnostic techniques used in veterinary medicine.

Hematopoietic neoplasia can be broadly classified as lymphoproliferative (lymphoid) or myeloproliferative (myeloid) disease, a distinction based on the fact that the earliest commitment of a pluripotent hematopoietic

## Pathologic Basis of Veterinary Disease, 4th Edition

stem cell is to either a lymphoid or nonlymphoid lineage (Fig. 13-1). Thus clonal proliferations of cells of lymphoid lineage are examples of lymphoid neoplasia, including the various forms of lymphoma (lymphosarcoma), lymphoid (lymphocytic) leukemia, and plasma cell tumors. Clonal proliferations of cells of nonlymphoid hematopoietic lineage (erythroid, granulocytic, monocytic and/or histiocytic, megakaryocytic), are considered myeloid neoplasias, including the various forms of myeloid (or myelogenous) leukemia, myelodysplastic syndrome, and histiocytic neoplasia. Mast cell tumors are not conventionally considered a form of hematopoietic neoplasia, but in a technical sense they are also a form of myeloid neoplasia.

A number of techniques for diagnosing and classifying hematopoietic neoplasia are becoming increasingly available for routine use in veterinary medicine. For example, *immunophenotyping* refers to the use of antibodies recognizing specific molecules expressed on different cell types to determine the identity of a cell population of interest. Immunophenotyping on the basis of these lineage-specific or lineage-associated markers can be performed on histologic sections (immunohistochemistry), air-dried cytology smears (immunocytochemistry), or by laser analysis of cells in suspension in blood or buffer solutions (flow cytometry). Another emerging diagnostic technique is the clonality assay, a PCR test that can help identify neoplastic lymphoid proliferations on the basis of clonal rearrangements of genes encoding lymphocyte antigen receptors. In terms of practical application, the clonality assay is most useful in helping to distinguish lymphoid neoplasia from nonneoplastic lymphoid proliferations mimicking neoplasia.

In the last several decades, as new diagnostic techniques have become available, numerous systems for classifying hematopoietic neoplasia in human beings have been proposed. These systems have been applied to veterinary medicine inconsistently but have helped to demonstrate the diversity of disease subtypes in animals. Some of these systems (the Rappaport and Kiel systems) did not attempt to correlate the classification of the neoplasm based on microscopic features with the clinical course of disease, whereas others (the Working Formulation for classification of lymphomas, sponsored by the National Cancer Institute) attempted to correlate survival data with morphologic criteria but did not take into account the cell of origin (i.e., B lymphocyte or T lymphocyte) of the tumor. The most recent (2002) published system for classifying hematopoietic neoplasia in animals is an adaptation of the 2001 World Health Organization (WHO) system in human beings. An effort is underway to coordinate the classification of hematopoietic neoplasia in human beings and animals in a consistent, clinically relevant manner. This effort, termed the American College of Veterinary Pathology (ACVP) Oncology Initiative, has two main components: a proposal for classification of canine lymphomas and a proposal for classification of myeloid neoplasia in cats and dogs. The ultimate goal of this undertaking is to correlate pathologic findings (cell morphology, immunophenotype, tissue architecture, anatomic location) precisely with clinical behavior of the neoplasm (prognosis, response to therapy).

The next section on hematopoietic neoplasia begins with leukemias (which may be of lymphoid or myeloid origin) and myelodysplastic syndromes, then covers the group of lymphoid malignancies known as lymphomas, and finishes by mentioning some other types of lymphoid and myeloid neoplasia.

13.2.1.6.1

### Leukemias and Myelodysplastic Syndromes

Leukemia is an umbrella term referring to malignant hematopoietic neoplasms that originate in the bone marrow and typically have significant numbers of neoplastic cells in the blood. Hematopoietic neoplasms originating in the spleen, but primarily manifested in the blood, are also considered by some to be forms of primary leukemia. The term *leukemia* is also sometimes used to refer to other forms of hematopoietic neoplasia originating outside of the bone marrow or spleen, such as lymphoma, that may progress to include significant bone marrow and blood involvement. For the purposes of this chapter, cases of

## Pathologic Basis of Veterinary Disease, 4th Edition

secondary bone marrow or blood involvement will not be considered leukemia but rather diseases with a “leukemic phase” of a primary disease other than leukemia. Although primary leukemias usually have high numbers of neoplastic cells in circulation, this is not always the case. Some forms of leukemia (especially acute lymphoid leukemia in cats) have very low numbers of circulating neoplastic cells. This situation is sometimes known as “aleukemic leukemia,” although very close examination of blood smears will usually reveal the underlying disease. The diagnosis may require confirmation by examination of the bone marrow, which in cases of leukemia contains disproportionately high numbers of neoplastic cells.

Table 13-5 Basic Classification of Leukemias

	Lymphoid	Myeloid
Chronic	CLL	CML
Acute	ALL	AML
ALL, Acute lymphoid leukemia; AML, acute myeloid leukemia; CLL, chronic lymphoid leukemia; CML, chronic myeloid leukemia.		

Leukemias are conventionally classified into one of four main groups according to cell type (lymphoid or myeloid, with subcategories of both types) and as chronic or acute (Table 13-5). Subcategories exist within each of these groups (e.g., lymphoid leukemias of B- or T-lymphocyte origin, and myeloid leukemias of erythroid, granulocytic, monocytic, or megakaryocytic origin). Chronic and acute leukemias differ both in terms of cell morphology and biologic behavior.

Chronic leukemias are proliferations of well-differentiated cells and are typically indolent, slowly progressive diseases. Often the number of neoplastic cells in circulation is very high. It is not unusual for the concentration to be in the hundreds of thousands per microliter. Mild to moderate nonregenerative anemia is common, but other cytopenias are not usually present. With chronic leukemias, the lineage of the cells is easy to identify by examining a blood or bone marrow smear. The cells look normal, or relatively normal, under the microscope. However, this can pose a diagnostic challenge because it is often not easy to tell whether the cells are a malignant population (i.e., leukemia) or a benign, reactive population (as in the case of marked inflammatory neutrophilia, reactive lymphocytosis, or secondary erythrocytosis), particularly when the concentration of cells in the blood is consistent with either neoplastic or nonneoplastic disease. Diagnosis of chronic leukemia in veterinary species is thus typically one of exclusion. An exception is when the concentration of cells in the blood is so high as to reasonably exclude the possibility of nonneoplastic disease (e.g., the concentration of lymphocytes in cases of chronic lymphocytic leukemia often exceeds 100,000 cells/uL). Necropsy findings are dependent on the stage of disease. In advanced cases with marked organ infiltration with neoplastic cells, there is often uniform splenomegaly, hepatomegaly, and lymphadenopathy. The bone marrow is highly cellular and, histologically, is densely cellular with well-differentiated neoplastic cells. In lymph nodes, there may be follicular lymphoid hyperplasia and neoplastic cells in the sinuses and medullary cords. Similarly the spleen may have follicular lymphoid hyperplasia and accumulation of neoplastic cells in the red pulp. The liver may have accumulations of neoplastic cells in the sinusoids and periportal areas.

Chronic lymphoid leukemias (CLLs) are uncommon in veterinary species. The disease is rarely reported in horses and poorly characterized in cattle. In dogs, CLL is predominantly a disease of middle-aged to older dogs. In the largest study to date, 73% of canine CLL cases were of T-lymphocyte origin. In 54% of the CLL cases, the neoplastic cells were granular T lymphocytes, the vast majority of which expressed CD8 (consistent with cytotoxic T-lymphocyte lineage). Interestingly, most of these cases apparently originated in the spleen, with detectable bone marrow involvement occurring relatively late in the course

## Pathologic Basis of Veterinary Disease, 4th Edition

of disease. There is scant published data regarding CLL in cats, but according to a recent report the majority of cases have a T-helper cell immunophenotype.

Chronic myeloid leukemias (CMLs) are rare in animals, with most reported cases occurring in dogs and cats. Types of CML reported in animals include chronic granulocytic leukemias of neutrophils, eosinophils, and basophils; chronic myelomonocytic leukemia; mast cell leukemia; essential thrombocythemia (CML of platelet lineage); and polycythemia vera (CML of erythrocyte lineage).

In contrast to chronic leukemias, acute leukemias are proliferations of poorly differentiated cells (Fig. 13-34) and typically have a rapid, aggressive clinical course. The distinction between chronic and acute leukemia is not always perfectly clear, either in terms of cell morphology or biologic behavior, and some cases fall “in the middle.” Moreover, chronic leukemia may develop into a more acute form (presumably because of additional mutation), a situation sometimes referred to as “blast crisis.” Acute leukemia has classically been defined by the presence of greater than 30% blast cells (large, immature cells) in the marrow or blood, although in human beings it has recently been proposed that the threshold be lowered to 20%. In general, the concentration of circulating neoplastic cells in acute leukemias does not tend to be as high as in chronic leukemias. Most animals with acute leukemia have cytopenias of two or more lineages, and pancytopenia is common. With acute leukemias, it is usually obvious from the presence of many large, immature cells in circulation that the patient has hematopoietic neoplasia. However, the cell of origin usually cannot be determined by routine microscopic examination because the cells are poorly differentiated. Identifying the specific cell type is best done by immunophenotyping and/or cytochemical staining. At necropsy, animals with acute leukemia have pale mucous membranes due to anemia, and the bone marrow is highly cellular. Other findings depend on the degree to which neoplastic cells have infiltrated organs. There is often uniform splenomegaly, sometimes with infarcts. Histologically the bone marrow is densely cellular with poorly differentiated neoplastic cells. The splenic red pulp may be extensively infiltrated with neoplastic cells. The lymph nodes may have minor involvement of the medullary cords to diffuse involvement of the entire node.

**Fig. 13-34 Acute leukemia, canine blood smear.** The specific lineage of the large, immature cells cannot be determined reliably based on routine staining. Wright's stain. (Courtesy Dr. M.M. Fry, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

*Myelodysplastic syndrome* (MDS) refers to a group of clonal myeloid proliferative disorders characterized by ineffective hematopoiesis. MDS does not meet the traditional definition of acute myeloid leukemia (AML) but is classically diagnosed based on these findings: less than 30% blasts in the bone marrow, cytopenias of more than one cell line, and morphologic evidence of dyshematopoiesis. Studies in people have shown that MDS also differs from AML on the molecular level (MDS is characterized by increased apoptosis compared with AML). MDS may lead to clinical illness and death as a result of the cytopenias and/or from transformation of the neoplasm into AML. MDS is rare in veterinary medicine, occurring most frequently in FeLV-infected cats.

The existing system for classification of AML and MDS in cats and dogs, an adaptation of the French-American-British (FAB) classification system in human beings, was proposed by the Animal Leukemia Study Group (ALSG) in 1991 and has been generally accepted since that time. However, the system does not include immunophenotyping or cytochemical staining characteristics, which have since become key aspects of classifying myeloid neoplasia in people. The ACVP Oncology Initiative group is currently working to develop a new classification system that includes immunophenotyping and cytochemical staining data. The mission of this group is as follows:

797

798

¼ to match a classification system (either the original system proposed by the Animal Leukemia Study Group or possibly a system modeled after the recently revised WHO system) with the biologic behavior of myeloid neoplasms. We hope to confirm or challenge the 30% blast cell threshold for distinguishing AML from MDS and associate biological behavior with specific disease subtypes. Similar to the revisions in the human classification system, this project must be done in collaboration with oncology clinics, veterinary institutions, and large diagnostic laboratories.

### 13.2.1.6.1.1

#### Box 13-10 Classification Systems for Acute Myeloid Leukemia

- Classification scheme proposed by Animal Leukemia Study Group in 1991: In Jain NC, Blue JT, Grindem CB et al: Proposed criteria for classification of acute myeloid leukemia in dogs and cats, *Vet Clin Pathol* 20(3):63-82, 1991.
- 2002 WHO Classification of the Myeloid Neoplasms: Vardiman JW, Harris NL, Brunning RD: *Blood* 100 (7):2292–2302, 2002.

The existing ALSG system in animals and the 2002 WHO classification system in human beings are referenced in [Box 13-10](#) and in the Suggested Readings list.

Acute lymphoid leukemia (ALL) is rarely recognized in horses and cattle. Cattle with lymphoid neoplasia caused by bovine leukemia virus infection often have high numbers of circulating neoplastic cells, but the disease is generally considered a form of lymphoma and will be discussed next in the section on lymphoma. In a recent immunophenotypic study of 38 cases of acute leukemia in dogs, 6 had B-lymphocyte ALL and 3 had T-lymphocyte ALL of CD8<sup>+</sup> granular lymphocytes. Cats with ALL often have low numbers of neoplastic cells in circulation, and examination of the bone marrow may be necessary to make the diagnosis.

AML occurs most often in dogs and cats but has also been reported in other domestic and wild animals. In dogs, the majority of acute leukemias are of myeloid or probable myeloid origin (21 of 38 cases in one recent study). Myelodysplastic syndrome is recognized most often in cats, especially in animals infected with FeLV, but has also been reported in dogs and horses.

### 13.2.1.6.2 Lymphoma (Lymphosarcoma)

The term *lymphoma* (also known as lymphosarcoma or malignant lymphoma) encompasses a diverse group of malignancies arising in lymphoid tissue(s) outside the bone marrow. There are many different forms, with notable variability in the following:

- Anatomic location—multicentric, alimentary, mediastinal/thymic, other
- Immunophenotype—B lymphocyte versus T lymphocyte versus non-B/non-T
- Cellular morphology—size, nuclear features, mitotic rate
- Histologic pattern—diffuse versus follicular
- Biologic behavior—from low-grade (indolent) to high-grade (aggressive) tumors

As mentioned previously, there is an ongoing effort within the ACVP to demonstrate the applicability of the new WHO system for classifying hematopoietic neoplasia in people to animals, including a specific project focusing on classification of lymphoma in dogs. The principle underlying this effort is that each category should constitute a distinct, recognized disease entity based on morphology, tissue architecture, immunophenotype, anatomic distribution, signalment data, and full clinical history. A critical component of this effort is to test the consistency (interobserver variability) and reproducibility (intraobserver variability) of interpretation.

#### 13.2.1.6.2.1 Diagnosis and laboratory findings

Lymphoma is often suspected on the basis of organomegaly (e.g., generalized lymph node enlargement) or abnormal ultrasound findings (e.g., thickened intestines with abnormal echogenicity). Initial diagnosis typically is made based on aspiration cytology, biopsy and/or histopathology, or both, of the affected organ(s). In both cytologic and histologic preparations, lymphoma is characterized by a monomorphic population of morphologically atypical lymphocytes. Histologically, lymphoma is also characterized by disruption of normal tissue architecture. In general, lymphomas of small, well-differentiated cells with low mitotic rates are low-grade (indolent, slowly progressive) diseases, whereas lymphomas of large, poorly differentiated cells with high mitotic rates are high-grade (aggressive, rapidly progressive) diseases (Fig. 13-35). The type of tumor and extent of disease may be characterized further by immunophenotyping and clinical staging, respectively. Immunophenotyping is done to determine whether a tumor is of B-lymphocyte or T-lymphocyte origin (this distinction cannot be made reliably based on routine staining). It is not necessarily the case that B-lymphocyte lymphomas have a more favorable prognosis than T-lymphocyte lymphomas because both cell types occur in low-grade and high-grade forms. Clinical staging includes examination of aspirates of bone marrow and other enlarged organs (e.g., spleen, liver, and other lymph nodes).

**Fig. 13-35 Grading of canine lymphomas, lymph node, dog.**

Lymphoma (lymphosarcoma): high grade, fine-needle aspirate (**A**), excisional biopsy (**B** and **C**). Neoplastic lymphocytes are large and have large nuclei with dispersed chromatin and prominent nucleoli. **Fig. 13-35, B and C** are low- and high-magnification images, respectively, of the same specimen. A mitotic figure is evident at the top right of **Fig. 13-35, C**. Wright's stain (**Fig. 13-35, A**), H&E stain (**Fig. 13-35, B and C**). Lymphoma (lymphosarcoma): low grade, fine-needle aspirate (**D**), excisional biopsy (**E** and **F**). Images were taken at the same magnifications as those shown in **Fig. 13-35, A to C**. In this sample, neoplastic lymphocytes are of small to intermediate size and have partially condensed chromatin. Wright's stain (**Fig. 13-35, D**), H&E stain (**Fig. 13-35, E and F**). Lymphoma (lymphosarcoma): low grade, immunohistochemistry (**G**) and clonality testing (**H**) results for the low-grade lymphoma case shown in **Fig. 13-35, D to F**. **Fig. 13-35, G** (from the same area shown in **Fig. 13-35, E**, and taken at the same magnification) shows immunostaining for the T-lymphocyte marker CD3, demonstrating a marked expansion of T lymphocytes. Polymerase chain reaction testing of DNA extracted from the excisional biopsy specimen confirmed that these cells had a clonal T-lymphocyte receptor gene rearrangement, as shown in the gel in **Fig. 13-35, H**. **Lane 1**, negative control with no DNA; **lanes 2 and 3**, duplicates of a different case of T-lymphocyte lymphoma; **lanes 4 and 5**, duplicates of this case; **lane 6**, positive control; **lane 7**, polyclonal control (i.e., normal). (**A**, Courtesy Dr. M.M. Fry, College of Veterinary Medicine, University of Tennessee. **B, C, E, F, and G**, Courtesy Dr. S.J. Newman, College of Veterinary Medicine, University of Tennessee. **D**, Courtesy Dr. D.F. Edwards, College of Veterinary Medicine, University of Tennessee. **H**, Courtesy Dr. W. Vernau, School of Veterinary Medicine, University of California, Davis.)

798

800

In cases of advanced disease there may be marked bone marrow and blood involvement, and distinguishing lymphoma from lymphoid leukemia can occasionally be difficult. The distinction can often be made on the basis of immunophenotyping—especially for CD34, which is usually expressed by neoplastic cells in acute leukemias and not in lymphomas. Other laboratory findings with lymphoma are variable. Mild to moderate nonregenerative anemia is probably the most common hematologic abnormality. Lymphopenia is noted more frequently than lymphocytosis, presumably because of abnormal trafficking of normal, nonneoplastic lymphocytes. Hypercalcemia is often associated with lymphoma due to production of parathyroid hormone-related peptide (PTHrP) by the neoplastic cells. Such paraneoplastic hypercalcemia (humoral hypercalcemia of malignancy) may lead to pathologic calcification and related complications (e.g., renal failure).

Necropsy findings in cases of multicentric lymphoma include enlarged lymph nodes that bulge on cut section and are gray-white to light tan or reddish. In advanced cases, the normal architectural distinction between the cortex and medulla is obliterated. Infiltration of spleen and liver can result in diffuse enlargement or nodules. In alimentary lymphoma, affected portions of the gastrointestinal tract are thickened and may be nodular. The lesions may be ulcerated. Enlarged mesenteric nodes may coalesce to form large masses. The gross appearance of thymic lymphoma is a large, gray, soft mass in the cranial mediastinum (Fig. 13-46). Renal lymphoma often affects both kidneys and is evident as bilateral diffuse renomegaly. Central nervous system and bone marrow involvement of lymphoma can be difficult to detect on necropsy because of the similar gross appearance of neoplastic and normal tissue. In any of the various forms of lymphoma, large masses may have areas of central necrosis.

### 13.2.1.6.2.2

#### Species differences

Lymphoma is the most common hematopoietic malignancy in animals and has been reported in all the domestic species.

Lymphoma is uncommon in horses, representing 5% or less of all neoplasms. Multicentric lymphoma is the most common form, and alimentary, cutaneous, and other forms may also occur. Most lymphomas in horses are of intermediate or low grade, according to most sources. The multicentric form is characterized by irregular involvement of peripheral lymph nodes with tumor masses in the mediastinum and abdomen. Lymph nodes in different anatomic regions (e.g., superficial, mediastinal, and alimentary) are often similarly affected, and infiltration of liver and spleen is common. Reports of the frequency of concurrent blood involvement vary from rare to more than 50%. The alimentary form of equine lymphoma is a wasting syndrome, presumably because of involvement of the small intestine, resulting in malabsorption. Cutaneous lymphoma in horses, as in other species, is a chronic disease without blood or internal organ involvement. Equine lymphoma is often of mixed cell type (B lymphocyte and T lymphocyte). B-lymphocyte tumors that also contain many nonneoplastic T lymphocytes (so-called T-lymphocyte-rich B-lymphocyte lymphoma) are especially common as subcutaneous neoplasms.

In cattle, lymphoma is primarily a multicentric B-lymphocyte disease of adult cattle and is strongly associated with BLV infection and BLV-related persistent lymphocytosis. Approximately 30% of cattle infected with BLV develop nonneoplastic persistent lymphocytosis, and of these, less than 5% develop lymphoma. The BLV-induced form of lymphoma is known as bovine enzootic lymphoma. BLV is a retrovirus that persists within lymphocytes for the life of the infected animal. Transmission of the virus is mostly horizontal due to transmission of infected lymphocytes as opposed to free virus in secretions. Blood-sucking arthropods or other mechanical means of transferring small numbers of infected lymphocytes (such as contaminated needles) are the principle means of spread. BLV infection is more common in dairy cattle than in beef cattle, presumably because dairy cattle husbandry favors viral transmission. Incidence of infection varies widely between regions and between herds. Antibodies against viral antigen can be detected by an agarose gel immunodiffusion test, and some herds remain free of BLV by testing and culling infected animals. In addition to lymph nodes, lymphoma in cattle often involves other locations, such as abomasum, vertebral canal, kidney, heart, retro-orbital space, and uterus (Fig. 13-36). Enlargement of superficial lymph nodes is common, and enlarged pelvic and abdominal lymph nodes are often found on rectal palpation. Involvement of the digestive tract and heart may cause vagal indigestion or diarrhea and congestive heart failure, respectively. Lymphoma of the central nervous system is most frequently manifested as posterior paresis or paralysis because of pressure by the extradural mass on the cauda equina or on the lumbar cord. Other sporadic forms of

## Pathologic Basis of Veterinary Disease, 4th Edition

lymphoma not associated with BLV infection also occur in cattle, including thymic, multicentric, and cutaneous forms affecting young animals. The thymic form of sporadic bovine lymphoma is characterized by large cranial thoracic and lower cervical masses, respiratory distress, and weight loss in cattle less than 2 years of age. The sporadic multicentric form is characterized by disseminated disease in calves 3 to 6 months of age. Affected calves frequently have widespread lymph node enlargement in addition to hepatic, splenic, and renal involvement. Marked blood and bone marrow involvement may also occur. The cutaneous form is rare, occurs in young cattle, and consists of discrete cutaneous plaques or large scabby lesions.

800

801

**Fig. 13-36 Lymphoma (lymphosarcoma), vertebral canal, epidural space, cow.** Bilateral ventrally located soft pink masses compress the spinal cord. In addition to lymph nodes, lymphoma in cattle often involves other locations, such as abomasum, vertebral canal, kidney, heart, retro-orbital space, and uterus. (Courtesy Dr. J.M. King, College of Veterinary Medicine, Cornell University.)

In dogs, lymphoma is a common form of neoplasia, representing approximately 7% to 9% of all malignancies and the large majority of hematopoietic malignancies. No retroviral or other cause is known. Lymphoma is typically a disease of middle-aged to older dogs. Multicentric lymphoma with generalized lymph node enlargement is the most common form (80% to 85% of all cases of canine lymphoma), and the majority of these (approximately 80%) are intermediate- or high-grade tumors. Other less common forms of canine lymphoma include alimentary, thymic, and cutaneous forms, and sporadically occurring forms in virtually every conceivable location. Approximately 70% to 80% of canine lymphomas are of B-lymphocyte origin. Although the remaining cases are mostly of T-lymphocyte origin, “null” (non-B, non-T, presumably of NK [natural killer] cell origin) lymphomas also occur. Clinical signs may be referable to the specific organ systems affected, but are usually absent or nonspecific when lymphoma is first diagnosed. Approximately 15% of dogs with lymphoma, and approximately 40% of those with mediastinal lymphoma, are hypercalcemic. In the majority of canine lymphoma cases, significant blood or bone marrow involvement is not detected by routine methods upon initial diagnosis, but may be seen with advanced disease. Splenic and hepatic involvement is common in cases of canine multicentric lymphoma.

## Pathologic Basis of Veterinary Disease, 4th Edition

In cats, lymphoma is among the many hematopoietic abnormalities caused by FeLV, and the epidemiology of feline lymphoma has changed with the development of routine vaccination and testing for FeLV. Cats infected with FeLV are likely to develop lymphoma at a younger age, and are more likely to develop certain types of lymphoma—especially mediastinal and multicentric T-lymphocyte forms—than FeLV-negative cats. These predispositions still apply, but the percentage of cats infected with FeLV has decreased dramatically. As a result, mediastinal (thymic) and multicentric forms of lymphoma, which used to represent the majority of cases, have become relatively uncommon. At present, approximately 80% to 90% of cats with lymphoma are FeLV-negative, and the majority of lymphoma cases are the alimentary form (Fig. 13-37). Other less common locations in cats include mediastinal, multicentric, renal, and other extranodal sites. FeLV-positive cats with lymphoma still tend to be younger, and their tumors more often of T-lymphocyte origin, than FeLV-negative cats. The large majority (>80%) of cats with mediastinal lymphoma, and approximately one third of cats with multicentric lymphoma, are FeLV-positive. Mediastinal and multicentric forms, although less common now, are still more likely to occur in younger cats, whereas the alimentary form typically develops in older cats (>10 years of age). The neoplastic cell type also tends to vary by anatomic location. Alimentary lymphoma in cats is predominantly a B-lymphocyte disease, whereas mediastinal lymphoma is predominantly a T-lymphocyte disease (consistent with thymic origin). A subtype of intestinal lymphoma in cats, large granular lymphocyte (LGL) lymphoma, is predominantly a T-lymphocyte disease with a highly aggressive biologic behavior. Unlike dogs, cats are usually clinically ill when lymphoma is first diagnosed. In addition to nonspecific signs, such as weight loss, anorexia, and poor grooming habits, cats often have signs referable to the affected organ systems. For example, animals with alimentary lymphoma often have chronic diarrhea and vomiting, and may have palpable abdominal masses, whereas those with mediastinal lymphoma are often dyspneic.

801

802

**Fig. 13-37 Alimentary lymphoma (lymphosarcoma), stomach, cat.** Note the notable thickening of the stomach, which occurred because of infiltration with neoplastic cells. Although uncommon, the mucosal epithelium is focally ulcerated. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Lymphoma is the most commonly reported malignancy in pigs and may be more likely to affect females than males. Multicentric lymphoma is the most common form of the disease in pigs. Lymph node enlargement is more common in visceral than peripheral nodes. Other commonly affected organs include spleen, liver, kidney, and bone marrow. Lymphoma often affects animals less than 1 year of age, and the mediastinal form of lymphoma tends to affect younger pigs more commonly than the multicentric form. A viral cause (C type viruses) for lymphoma in pigs has been suggested, but transmission studies are lacking. A form of hereditary multicentric lymphoma has also been reported in inbred herds.

### 13.2.1.6.3 Other Forms of Hematopoietic Neoplasia

In addition to the leukemias and lymphomas, other forms of hematopoietic neoplasia—including lymphoid neoplasms (plasma cell tumors) and myeloid neoplasms (histiocytic, mast cell, and granulocytic tumors)—are also recognized in animals.

#### 13.2.1.6.3.1 Plasma cell neoplasia

There are two main forms of plasma cells tumors recognized in veterinary species: multiple myeloma (MM) and plasmacytoma.

##### 13.2.1.6.3.1.1 Multiple myeloma.

MM is a malignant tumor of plasma cells that arises in the bone marrow and usually secretes large amounts of immunoglobulin (Ig). Blood involvement of the neoplastic cells is not a feature of the disease. MM is a rare disease in animals. Dogs are affected more frequently than other species, but MM has also been reported in horses, cattle, cats, and pigs. The hallmark laboratory finding in patients with MM is hyperglobulinemia, which occurs because of production of large amounts of Ig or Ig subunit by the neoplastic cells. This homogenous protein fraction is often called paraprotein or M protein. Concentrations of other Igs are often decreased.

Diagnosis of MM is based on finding a minimum of two or three (opinions vary) of the following abnormalities:

- Markedly increased numbers of plasma cells in the bone marrow, especially in aggregates (Fig. 13-38, A). A threshold value of plasma cells constituting at least 30% of nucleated cells in the marrow has been proposed as a diagnostic criterion. The neoplastic cells composing the tumor may be well-differentiated plasma cells or poorly differentiated cells with increased anisocytosis and anisokaryosis, visible nucleoli, and multinucleation.
- Monoclonal gammopathy because of clonal production of Ig or Ig fragments by the neoplastic cells. Monoclonality is demonstrated by serum protein electrophoresis (Fig. 13-38, B), and can be characterized further using immunodiagnostic techniques (see later discussion). The term “gammopathy” is used because most Igs migrate in the  $\gamma$ -region of an electrophoresis gel, although some (especially IgA and IgM) may migrate in the  $\beta$ -region. Occasionally biclonal or other atypical electrophoretic patterns may be seen with MM as a result of protein degradation, complex formation, or binding to other proteins, or when the tumor includes more than one clonal population. It is important to note that monoclonal gammopathy is not

802

803

## Pathologic Basis of Veterinary Disease, 4th Edition

---

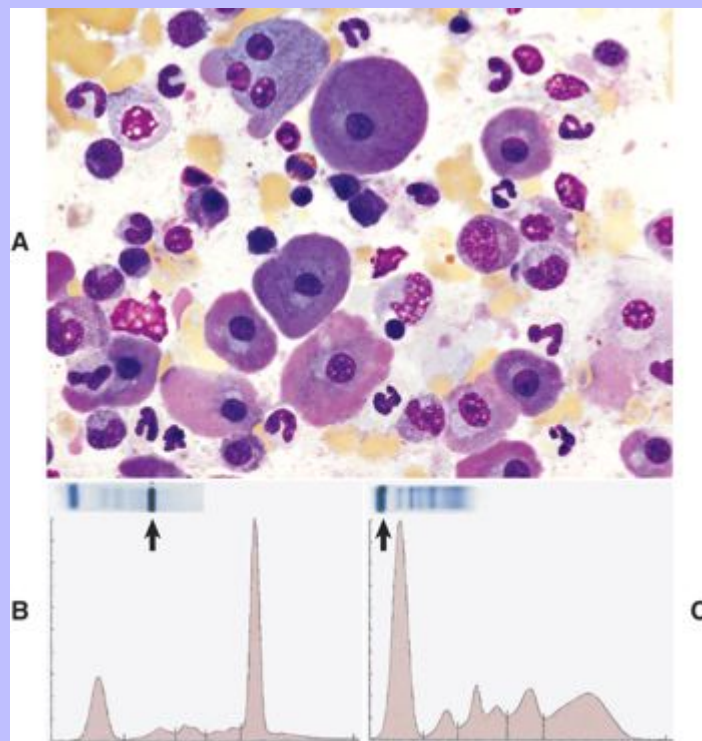

specific to MM but has also been reported in cases of B-lymphocyte lymphoma and some nonneoplastic conditions, such as canine ehrlichiosis or leishmaniasis. What appears to be a monoclonal pattern in the  $\gamma$ -region on routine serum electrophoresis may actually be oligoclonal (i.e., may include several Igs with a very similar migration pattern that are increased because of an immunologic response to antigenic stimulation). (This is unlikely to be the case with “spikes” in the  $\beta$ -region, because nonneoplastic conditions typically do not result in high concentrations of IgA or IgM.) Definitively distinguishing monoclonal from oligoclonal patterns in the  $\gamma$ -region requires immunoelectrophoresis or immunofixation using species-specific antibodies recognizing different Ig subclasses and subunits.

- Radiographic evidence of osteolysis. Recent work with human cell cultures has shown that osteoclasts support the growth of myeloma cells, and that direct contact between the two cell types increases the myeloma cell proliferation and promotes osteoclast survival.
- Light chain proteinuria. Free Ig light chains (Bence-Jones proteins) are of low molecular weight and pass through the glomerular filter into the urine. These proteins do not react with urine dipstick protein indicators and are most specifically detected by electrophoresis and immunoprecipitation.

Other pathologic findings in patients with MM may include the following:

- Hypercalcemia, most likely due to increased osteoclast activity
- Lesions associated with marked hyperglobulinemia (hemorrhage caused by secondary platelet dysfunction, renal amyloidosis, and hyperviscosity syndrome)
- Cytopenias due to high numbers of neoplastic cells in the bone marrow

**Fig. 13-38 Multiple myeloma and monoclonal gammopathy. A,** Canine bone marrow aspirate. Many of the neoplastic plasma cells in the bone marrow aspirate have pink-tinged cytoplasm, the result of a high concentration of immunoglobulin. Wright's stain. **B,** Multiple myeloma, cat. Agarose gels and densitometry tracings showing results of serum electrophoresis. The serum has a high concentration of a monoclonal immunoglobulin (*the dark band [arrow] on the right of the gel, corresponding to the tall peak on the right of the tracing*). **C,** Normal cat. Agarose gels and densitometry tracings showing results of serum electrophoresis. The serum has a normal distribution of protein fractions, the most abundant being albumin (*the dark band [arrow] on the left of the gel, corresponding to the tall peak on the left of the tracing*). ## Pathologic Basis of Veterinary Disease, 4th Edition

MM typically has a slowly progressive clinical course. Common sites of metastasis include the spleen, liver, lymph nodes, and kidneys.

### 13.2.1.6.3.1.2

#### Plasmacytomas.

Cutaneous plasmacytomas are solid tumors of plasma cell origin that involve the skin or mucous membranes. Masses may be single or multiple. These tumors are usually benign, and excision is usually curative, but more aggressive forms may occur. Cutaneous plasmacytoma is discussed in more detail in [Chapter 17](#). The tumor type known as extramedullary plasmacytoma (EMP) is a malignant solid tissue tumor of plasma cells arising from sites other than the bone marrow. The tumor is rare in animals, occurring most often in dogs and also reported in horses and cats. In one study, there was a disproportionately high percentage of EMP cases in cocker spaniels. The tumors occur most frequently in the gastrointestinal tract but may also occur in the trachea, spleen, kidney, uterus, central nervous system, and elsewhere. Grossly the tumors may be multinodular or cause thickening of the intestinal wall. Metastasis to regional lymph nodes is common. As with MM, the neoplastic cells composing the tumor may be well-differentiated to poorly differentiated ([Fig. 13-39](#)). EMPs produce monoclonal immunoglobulins, and monoclonal gammopathy has been reported in some cases of EMP. If there is bone or bone marrow involvement of a malignant plasma cell tumor, it is considered to be MM. Amyloidosis is associated with EMP in many reports and may be useful in distinguishing extramedullary plasmacytoma from other tumors. The distinction between cutaneous plasmacytoma and extramedullary plasmacytoma is not always clear, and benign plasmacytomas of the skin have also been referred to as cutaneous extramedullary plasmacytomas.

**Fig. 13-39 Plasmacytoma, oral mucosa, dog.** Note the moderately well-differentiated plasma cells arranged in small clusters separated by a fibrovascular stroma. H&E stain. (*Courtesy College of Veterinary Medicine, University of Illinois.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 13.2.1.6.3.2 Histiocytic neoplasia

#### 13.2.1.6.3.2.1 Histiocytoma.

Histiocytoma, a benign cutaneous neoplasm of epidermal Langerhans cell origin, is discussed in detail in [Chapter 17](#).

#### 13.2.1.6.3.2.2 Histiocytic sarcoma.

Histiocytic sarcoma (HS) is an uncommon malignant neoplasm of histiocytic (macrophage or dendritic cell) origin. It occurs most frequently in the dog but has also been reported in the cat. There is a general belief that rottweilers and Bernese mountain dogs are at increased risk for HS, although good epidemiologic data is thus far lacking. Some have called the disseminated form of this disease, with multiple organ involvement, by the name “malignant histiocytosis,” reserving the term “histiocytic sarcoma” for cases of single solid tumors, but there is an emerging consensus that the latter term encompasses both forms of the disease. The disseminated form of the disease has a rapid, aggressive clinical course. Sites commonly involved include the spleen, lung, lymph nodes, bone marrow, skin, and subcutis. Liver involvement occurs secondary to disease in the spleen. The solitary form of HS can occur at any of the aforementioned sites, and also in joints (in close association with the subsynovium) or brain. Most cases of HS are of dendritic antigen-presenting cell origin, with a similar immunophenotype to (but dramatically different biologic behavior than) cutaneous histiocytoma. Fewer cases of HS are of macrophage cell origin. These malignant cells have an immunophenotype characteristic of resident macrophages in the splenic red pulp and the bone marrow, and frequently show marked phagocytosis of erythrocytes (hemophagocytosis). Dogs with this form of HS frequently have a hemophagocytic syndrome characterized by severe nonregenerative to mildly regenerative anemia (presumably due largely to destruction of RBCs by the neoplastic cells), splenomegaly, hepatomegaly, and extramedullary hematopoiesis in the spleen and elsewhere. Microscopically, HS tumor cells are large, round to spindloid in shape, and vary from relatively well-differentiated histiocytic morphology to cells with notable features of malignancy ([Fig. 13-40](#)).

803

804

#### 13.2.1.6.3.2.3 Cutaneous and systemic histiocytoses.

Cutaneous histiocytosis (CH) and systemic histiocytosis (SH) are actually nonneoplastic canine immunoregulatory disorders, rather than hematopoietic neoplasms. They are included in this section because of their clinical similarities with histiocytic neoplasia. CH, a rare disease caused by proliferation of activated dermal dendritic cells, is discussed in more detail in [Chapter 17](#). SH is a familial disorder of Bernese mountain dogs (also found sporadically in other breeds) characterized by large, dense proliferations of activated interstitial dendritic cells in multiple tissues, including skin, peripheral lymph nodes, and ocular and nasal mucosa. The proliferating cells are immunophenotypically identical to those in CH, and the angiocentric skin lesions in SH are histologically identical to those in CH. Lesions of SH in locations other than skin are also angiocentric infiltrates consisting mostly of histiocytes and lymphocytes.

### Mast cell neoplasia

Mast cell tumors (MCTs) of the skin and other organs are relatively common in animals, especially in dogs, and are covered in other chapters in this book. Primary leukemia of mast cell origin is a rare form of myeloid leukemia. Mast cells normally are not present in circulation, but the finding of mast cells in the blood (mastocytemia) does not necessarily indicate myeloid neoplasia. In fact, one study found that severity of mastocytemia in dogs was frequently higher in animals without MCTs than those with MCTs, and that random detection of mast cells in blood smears usually is not due to underlying MCT.

**Fig. 13-40 Histiocytic sarcoma, canine mesenteric lymph node.** The neoplastic cells are round cells with abundant gray-blue cytoplasm. Note the following features of malignancy: **A**, The low-magnification image shows notable variation in cell and nuclear sizes. **B**, The high-magnification image shows multinucleation, prominent nucleoli, and mitotic figures, as well as a background population of lymphocytes. Wright's stain. (*A and B* Courtesy Dr. M.M. Fry, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

13.2.1.6.3.4

### Granulocytic sarcoma

There are rare reports in animals of extramedullary solid tumors of granulocytic origin, known as granulocytic or myeloid sarcomas. These tumors are poorly characterized.

13.2.1.7

### COAGULATION DISORDERS

The section focuses on acquired and inherited primary disorders of coagulation and also includes a secondary condition, disseminated intravascular coagulation (DIC), which is characterized clinically by abnormal hemostasis.

804

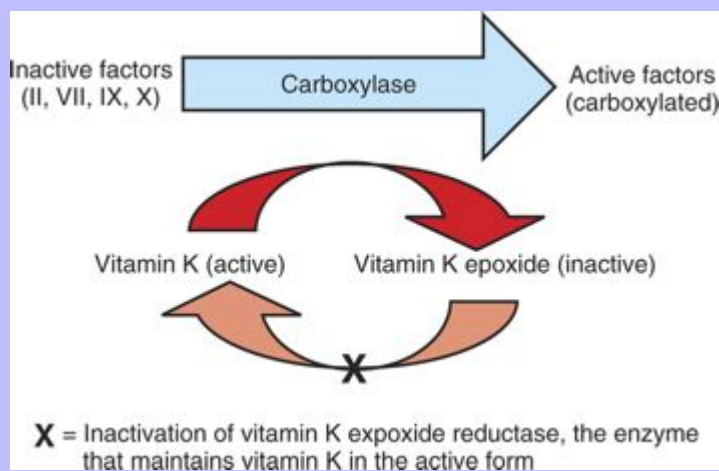

13.2.1.7.1

### Avitaminosis K

805

A number of coagulation factors (factors II, VII, IX, and X, as well as the regulatory molecules Protein C and Protein S) must undergo carboxylation to be functional. This posttranslational modification is catalyzed by the enzyme  $\gamma$ -glutamyl carboxylase and requires vitamin K as a cofactor. Vitamin K is oxidized during the carboxylation reaction and is converted back into its active reduced form by the enzyme vitamin K epoxide reductase. The factors requiring this carboxylation step are thus vitamin K dependent, and deficiency or antagonism of vitamin K leads to production of nonfunctional factors and resulting coagulopathy (Fig. 13-41). Conditions associated with avitaminosis K include poisoning with coumarin-related molecules; fat malabsorption (vitamin K is one of the fat-soluble vitamins) due to primary intestinal disease or impaired biliary outflow (uncommon); dietary deficiency (rare); and antibiotics that interfere with vitamin K absorption or usage. Coumarin-related rodenticides, such as warfarin, act by inhibiting vitamin K epoxide reductase, resulting in an absence of vitamin K in its active reduced form. This inhibition lasts until the rodenticide is metabolized and cleared. How long this takes depends on the half-life ( $t_{1/2}$ ) of the rodenticide and dose, but it may take many weeks. Second-generation rodenticides, such as bromadiolone and brodifacoum, are more potent than warfarin, with a longer  $t_{1/2}$ . Mycotoxins in the same family as anticoagulant rodenticides are associated with mildly sweet clover or sweet vernal grass and cause coagulopathy by the same mechanism. Laboratory findings include prolonged coagulation times (prothrombin time [PT], partial thromboplastin time [PTT], and activated clotting time [ACT]). Early in the course of rodenticide and related toxicoses, PT may be the only one of these tests that is prolonged, because factor VII has the shortest  $t_{1/2}$  of the vitamin K-dependent factors, but the other tests will become prolonged as nonfunctional forms of the other factors accumulate. In uncomplicated cases, patients are not thrombocytopenic. A wide range of hemorrhagic lesions may occur in affected individuals, including ecchymoses, epistaxis, gingival bleeding, hematomas, hemoptysis, melena or hematochezia, hematuria, and other forms of hemorrhage. The treatment for cases of rodenticide and related toxicoses is regular administration of exogenous vitamin K<sub>1</sub> until the toxin is cleared (determined by repeat coagulation testing after withholding treatment).

Fig. 13-41 **Schematic diagram of the mechanism of anticoagulant rodenticide toxicity.** Anticoagulant rodenticides inhibit the enzyme that converts vitamin K back to its active reduced form.

### 13.2.1.7.2 Disseminated Intravascular Coagulation

DIC is a syndrome characterized by continuous activation of both coagulation and fibrinolytic pathways. Also known as “consumptive coagulopathy,” DIC is not a primary disease process, but rather a secondary complication of many types of underlying disease. It is common in critically ill domestic animals. DIC involves an initial hypercoagulable phase, resulting in thrombosis and ischemic tissue damage, and a subsequent hypocoagulable phase as a result of consumption of coagulation factors and platelets, resulting in hemorrhage (Fig. 13-42). The list of underlying conditions associated with DIC includes neoplasia, sepsis, endotoxemia, immune-mediated disease, intravascular hemolysis, shock, heat stroke, and obstetric complications. The pathogenesis of DIC typically involves the release of tissue factor (thromboplastin) and subsequent activation of coagulation pathways and platelets but may also involve defective normal inhibition of coagulation or defective fibrinolysis. Classically, diagnosis of DIC is based on clinical evidence of hemorrhage and/or thromboembolic disease and a triad of laboratory findings: thrombocytopenia, usually moderate (below the lower reference value, but above 50,000/ $\mu$ L); prolonged coagulation times (PT and/or PTT); and decreased fibrinogen, or increased concentration of plasma fibrin degradation products or D-dimer. Milder forms of DIC that do not meet all of the diagnostic criteria also occur. Decreased plasma antithrombin (antithrombin III) concentration and schistocytosis are other laboratory abnormalities often found in patients with DIC.

### 13.2.1.7.3 Inherited Coagulation Disorders

#### 13.2.1.7.3.1 Hemophilia A and B

*Hemophilia A* refers to an inherited deficiency of functional coagulation factor VIII and has been recognized in horses, cattle, dogs, and cats. *Hemophilia B*, also known as Christmas disease, refers to an inherited deficiency of functional coagulation factor IX and has been recognized in dogs and cats.

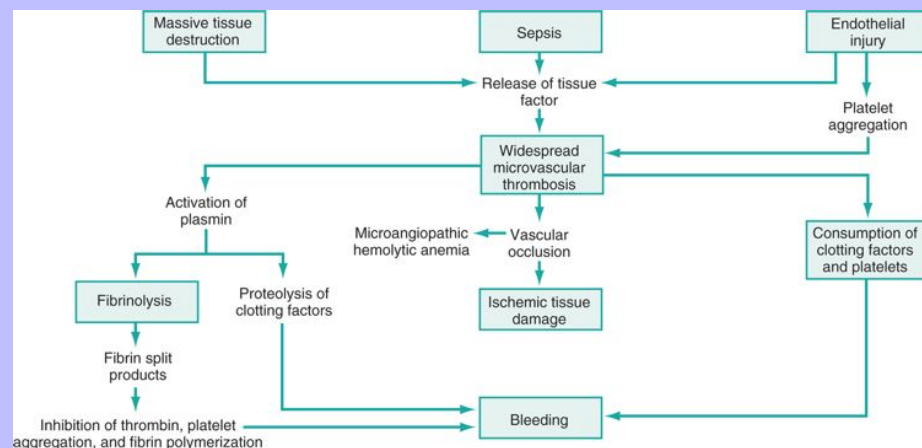

805

## Pathologic Basis of Veterinary Disease, 4th Edition

Both forms of hemophilia have an X-linked recessive mode of inheritance. Affected males have variable tendencies to bleed, depending on the severity of the deficiency, exposure to trauma, and size and activity level of the affected individual. Carrier females are usually asymptomatic.

806

**Fig. 13-42 Schematic diagram of the pathophysiology of disseminated intravascular coagulation.** (From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

13.2.1.7.3.2

### Other inherited factor deficiencies

Factor XI deficiency is the most common inherited coagulopathy in cattle and has also been reported in dogs. The mode of inheritance is probably autosomal recessive. Reports describe excessive bleeding in affected individuals after surgery. The most commonly affected dog breed is the Kerry blue terrier. In these dogs, hemorrhage is often delayed, sometimes developing several days after surgery. Other factor deficiencies also have been reported in animals. These conditions include deficiencies of factor VII (reported in dogs), factor XII (relatively common in cats, also reported in dogs), and prekallikrein (reported in dogs and horses). In most cases, affected individuals are asymptomatic or have only mild clinical bleeding tendencies but may have excessive bleeding following trauma or surgery.

13.2.1.7.3.3

### Other inherited coagulopathies

A defect in  $\gamma$ -glutamyl carboxylase, the enzyme required for normal carboxylation of vitamin K-dependent clotting factors, has been recognized as the cause of an inherited coagulopathy in Rambouillet sheep.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 13.2.2 LYMPHATIC SYSTEM

#### 13.2.2.1 DISORDERS OF THE THYMUS

##### 13.2.2.1.1 Congenital Disorders

Included in this description are the congenital disorders that result in inadequate T-lymphocyte function, and those resulting in B-lymphocyte and plasma cell dysfunction. Many have been described in human beings, and indeed have been invaluable in learning more about mechanisms of immunity and immune regulation. The animal counterparts of immunodeficiency serve as valuable models in comparative immunology research. Combined immunodeficiency disorders (CIDs) are those affecting both humoral and cell-mediated immunity (B and T lymphocytes).

Equine CID is a genetic disorder occurring in Arabian or part-Arabian foals. There is failure of functional B- and T-lymphocyte production, so foals are remarkably susceptible to a variety of microbial agents and usually die before 5 months of age. Adenoviruses that are typically resisted by normal foals are a major cause of death in foals with CID. The viral infection is frequently complicated by various bacterial or protozoal infections that typically result in pneumonia.

Necropsy findings are severe bronchopneumonia in combination with a small thymus, spleen, and lymph nodes. The thymus may be difficult to identify or may consist of a few isolated lobules within the mediastinal fat. Microscopically, it usually consists of a few islands of lymphocyte-like cells and thymic corpuscles. The spleen is smaller than normal because of a marked reduction in the white pulp owing to absence of germinal centers (Fig. 13-43) and periarteriolar lymphoid sheaths. Peripheral lymph nodes and internal lymph nodes may be small and difficult to identify because of the absence of lymphocytes.

806

807

**Fig. 13-43 Combined immunodeficiency disease, spleen, foal.** The large pale pink areas are splenic trabeculae. Note the almost total absence of white pulp. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

X-linked severe combined immunodeficiency (XSCID) has been reported in basset hounds. The affected male pups lack mature functional T lymphocytes. The animals have a normal serum level of IgM but low or undetectable IgG and IgA. The thymus of these dogs is small and often obscured by mediastinal fat. Tonsils, lymph nodes, and Peyer's patches usually cannot be identified at necropsy. Microscopically the thymic tissue consists of small dysplastic lobules with a variable number of Hassall's corpuscles. XSCID has also been described in Jack Russell terrier and Welsh corgi breeds of dogs.

Thymic cysts can be found within the developing and mature thymus and in thymic remnants in the cranial mediastinum. These cysts are often lined by ciliated epithelium and represent developmental remnants of branchial arch epithelium and are usually of no significance.

13.2.2.1.2

### Inflammatory and Degenerative Disorders

Thymitis, an infrequent lesion, is seen in porcine circovirus 2 infection (postweaning multisystem wasting syndrome [PMWS]), enzootic bovine abortion (EBA), and salmon poisoning disease of dogs. In PMWS there are multifocal noncaseating granulomas with giant cells, in EBA there is diffuse infiltration of macrophages in both the medulla and septa, and in canine salmon poisoning disease there is infiltration of neutrophils and macrophages into the cortex and medulla of the thymus.

**Fig. 13-44 Equine herpesvirus 1, spleen, aborted foal.** Most of the splenic follicle is occupied by nuclear debris, the result of lymphocytolysis. The splenic follicle is surrounded by a small rim of red pulp. H&E stain. (*Courtesy College of Veterinary Medicine, University of Illinois.*)

Injury to the thymus resulting in variable degrees of acquired immunodeficiency may be caused by infectious agents (viruses), toxins, chemotherapeutic agents and radiation, malnutrition, aging, and neoplasia.

## Pathologic Basis of Veterinary Disease, 4th Edition

Viruses damaging the thymus, and often other lymphoid tissues, include canine distemper virus, equine herpesvirus 1 (EHV-1) in aborted foals (Fig. 13-44), feline parvovirus, feline immunodeficiency virus, bovine viral diarrhea virus (BVDV) and hog cholera virus. Lymphocytolysis of the cells of the germinal centers and cortex occurs in feline panleukopenia and in the germinal centers in EHV-1 and BVD infections. In kittens infected with FIV, thymic depletion is an early lesion, and in kittens with progressive FIV infection, ultimately there is complete loss of thymic architecture with only minimal thymic tissue remaining in the connective and adipose tissue.

Environmental toxins such as halogenated aromatic hydrocarbons (e.g., polychlorinated biphenyls and dibenzodioxins, lead, and mercury) have a suppressive effect on the immune system. Fumonisin B<sub>1</sub> and B<sub>2</sub>, which are secondary fungal metabolites produced by members of the genus *Fusarium*, cause lymphocytolysis in the thymic cortex. In weaner and grower pigs, aflatoxin causes thymic atrophy because of lymphocyte depletion. In the case of the halogenated aromatic hydrocarbons, there is a genetic basis for susceptibility that is mediated through a complex composed of the aromatic hydrocarbon receptor and the aromatic receptor nuclear transporter. In general, these chemicals cause severe atrophy of the primary and secondary lymphoid organs. Other environmental toxins, such as the metals lead and mercury, cause toxic effects through the interaction of the metal with an enzyme system, cell membrane, or organelle. Similarly, therapeutic agents in general specifically target enzyme systems and cellular components essential for cell replication. Thus they can cause inhibition of a cellular function rather than cause a morphologic change.

807

808

**Fig. 13-45 Effect of ionizing radiation, atrophy of the thymus, cortex and medulla. A, Normal thymus.** The cortex is heavily populated with numerous thymocytes. The medulla (*bottom right*) contains fewer of these cells. H&E stain. **B, Thymus exposed to ionizing radiation.** Note the depletion of lymphocytes in both cortex and medulla and the preservation of Hassell's corpuscles (pink, concentric layers). H&E stain. (**A and B**, From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Treatments with anticancer drugs, radiomimetic drugs, or ionization radiation can result in immunosuppression. Lymphocytes are very sensitive to these agents. Therapies that cause immunosuppression are best illustrated by the cytotoxic drugs used as chemotherapeutics to treat cancer. In general most cytotoxic drugs inhibit cell division by mechanisms that are centered on the function and activity of nucleic acids. Purine analogs (e.g., azathioprine) compete with purines in the synthesis of nucleic acids, whereas alkylating agents like cyclophosphamide cross-link DNA and inhibit the replication and activation of lymphocytes. Cyclosporin A specifically inhibits the T-lymphocyte signaling pathway by interfering with the transcription of the IL-2 gene. Methotrexate, a folic acid antagonist, blocks the synthesis of thymidine and purine nucleotides. As chemotherapeutics, they have the beneficial effect of targeting cancer cells and the detrimental effect of also targeting noncancerous immune cells—resulting in immunosuppression, the proverbial double-edged sword. Because of the desirable effect of these and other drugs, they are used in the prevention of allograft rejection reactions following transplantation. Corticosteroids are considered to be immunosuppressive, although the degree of suppression is highly variable among species, and, in general, human beings and rodents are corticosteroid sensitive, whereas domestic species are considered corticosteroid resistant.

Ionizing radiation exerts its effects, in part, through lethal mechanisms that target components of DNA and through nonlethal mechanisms related to the generation of highly reactive free radicals. Ionizing radiation can damage lymphoid tissues and cells (Fig. 13-45).

Malnutrition impairs thymic function because it rapidly induces thymic atrophy, with resultant reduction in thymic hormone output. The effect is a reduction in the number of circulating T-lymphocytes in the blood, depletion of T-lymphocytes from the secondary lymphoid organs, and impairment of T-lymphocyte functions. This effect of starvation is mediated by the hormone leptin, whose concentration in the blood is proportional to the mass of fat in the body. Consequently its blood concentration is reduced in starvation, and immunosuppression results.

13.2.2.1.2.1

### Aging

With advancing age, all lymphoid organs become reduced in size (atrophic) and have reduced lymphocyte populations. In the case of the thymus, this reduction in size occurs normally after sexual maturity and is more appropriately termed thymic involution. The term *involution* should be reserved for normal physiologic processes in which an organ either returns to normal size after a period of enlargement (e.g., postpartum uterus) or regresses to a more primitive state (e.g., thymic involution) (see previous discussion on gross examination of the thymus). Atrophy, although most commonly used to denote a pathologic decrease in the size of a cell, tissue, or organ, can also be used to indicate a decrease in size of an organ that is dependent on hormonal stimulation. Stated simply, involution should be reserved for nonpathologic physiologic processes, whereas atrophy may or may not imply a pathologic process.

Fig. 13-46 **Lymphoma (lymphosarcoma), thymus, dog.** The large pale mass in the cranial mediastinum is a thymic lymphosarcoma that has displaced the lungs caudad. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

808

13.2.2.1.3

### Neoplasia

809

Because the thymus has both lymphoid and epithelial components, it is possible for either or both to serve as cells of origin of neoplasms. Thymic lymphoma (Fig. 13-46) is a T-lymphocyte neoplasm of young animals, particularly in cats and cattle and less frequently seen in dogs (see Hematopoietic Neoplasia). Clinical findings reflect the presence of a large mass in the cranial mediastinum. This mass can often be forced into the thoracic inlet with gentle compression of the cranial ribs.

Bovine thymic lymphoma most often occurs in beef cattle 6 to 24 months of age and is characterized by massive thymic enlargement. The cause is unknown, and the occurrence of a concurrent leukemia is unusual. The thymus is an important site of lymphoma in cats. The tumors are large white or gray mediastinal masses that result in displacement of adjacent structures and in pleural fluid accumulation. In cats, the fluid is frequently chylous. Microscopically, these diffuse lymphomas are dominated by lymphocytes, which are homogeneous in size, shape, nuclear morphology, and nuclear-cytoplasmic ratio.

Thymomas are usually benign neoplasms that occupy the cranial mediastinum, usually of older animals. They are significantly less common than thymic lymphoma and are only distinguishable microscopically by the presence of neoplastic epithelial cells. Lymphocytes are present within thymomas but are not neoplastic. Thymomas have been associated with myasthenia gravis (which may be accompanied by megaesophagus) and polymyositis (immune-mediated) in dogs. A rare condition, thymic hyperplasia, which results from the formation of B-lymphocyte follicles within the thymus, has also been reported in association with myasthenia gravis in dogs and cats.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 13.2.2.1.4 Miscellaneous

#### 13.2.2.1.4.1 Thymic hematomas

Thymic hemorrhage and hematomas have been reported in dogs. Many of these die unexpectedly from hypovolemic shock as a result of massive thymic and mediastinal hemorrhage. A variety of causes has been implicated. These include rupture of dissecting aortic aneurysms, trauma from automobile accidents, and ingestion of anticoagulant rodenticides (warfarin, dicumarol, diphacinone, and brodifacoum). In the last type, hemorrhage causes expansion of thymic lobules and interlobular septa and appears to originate in the medulla.

Grossly hemorrhage or hematomas may be confined to the thymus or extend into the mediastinum. In anticoagulant rodenticide poisoning, hemorrhages may also be at other sites, including the pericardial sac, mesentery, liver, and peritoneum.

### 13.2.2.2 DISORDERS OF THE SPLEEN\*

#### 13.2.2.2.1 Congenital Disorders

Asplenia or the failure of a spleen to develop in utero occurs occasionally in animals. This finding is usually incidental. Because congenital asplenia is so rare, it is not entirely clear whether this affects the resistance of domestic animals to disease. The condition is well known in certain strains of mice, but these are usually maintained under either germ-free or specific pathogen-free (SPF) conditions. However, congenitally asplenic mice have a high mortality rate to experimental plasmodium infection.

Congenital immunodeficiency diseases have been described in Disorders of the Thymus.

\* The authors acknowledge Dr. W.L. Spangler for editing this section of the chapter.

#### 13.2.2.2.2 Splenomegaly

Although the following conditions have been discussed on the basis of whether or not they cause splenomegaly, it is important to realize that in the early stages, the process involved may not have had sufficient time to cause splenomegaly or splenic nodules.

The diseases and disorders associated with splenomegaly will be discussed using the following categories:

- Uniform splenomegaly with a bloody consistency—bloody spleen (Fig 13-47, A)
- Uniform splenomegaly with a firm consistency—meaty spleen (Fig 13-47, B)
- Splenic nodules with a bloody consistency
- Splenic nodules with a firm consistency
- Small spleens

Table 13-3 lists the common causes of uniform splenomegaly.

809

Fig. 13-47 **Uniform splenomegaly.** **A**, Congested bloody spleen. This condition occurs secondary to compromises in vascular flow into and out of the spleen (e.g., torsion), from intravenous barbiturates (e.g., euthanasia or anesthesia), and from acute hyperemia from septicemia. **B**, Meaty spleen. This condition most commonly results from proliferation of cells, most frequently macrophages in the red pulp and increased splenic phagocytosis in, for example, septicemias and bacteremias. (*A and B Courtesy College of Veterinary Medicine, University of Illinois.*)

13.2.2.2.1

Uniform splenomegaly with a bloody consistency—"bloody" spleen

The common causes of a bloody spleen are congestion (torsion, barbiturate euthanasia, anesthesia), acute hyperemia (inflammation, anthrax), and acute hemolytic anemia.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

13.2.2.2.2.1.1

### Congestion

13.2.2.2.2.1.1.1

#### Torsion.

Torsion of the spleen occurs mainly in pigs and dogs, and torsion of the spleen and stomach together occurs in dogs, usually deep-chested ones (see [Chapter 7](#)).

In contrast to ruminants, in which the spleen is firmly attached to the rumen, the spleen of dogs and pigs is attached loosely to the stomach by the gastrosplenic ligament. It is the twisting of the spleen on this ligament that results initially in occlusion of the veins, causing splenic congestion, and later in occlusion of the artery, causing splenic infarction.

Grossly the spleen is uniformly and markedly enlarged and blue-black from cyanosis ([Fig. 13-47, A](#)). It is often folded back on itself (visceral surface to visceral surface) in the shape of the letter “C.” Treatment for this is splenectomy, but removal of the spleen renders the animal susceptible to certain organisms, such as hemotropic mycoplasma infections (previously known as haemobartonellosis and eperythrozoonosis) in dogs and cattle, and babesiosis and theileriosis in cattle in endemic areas.

13.2.2.2.2.1.1.2

#### Barbiturate euthanasia, anesthesia, or sedation.

Acute passive congestion is seen most dramatically at necropsy in horses and dogs that have been euthanized or anesthetized by intravenous injection of barbiturate. When a dog under barbiturate anesthesia and with a markedly congested spleen from the anesthetic was injected with 1 ml of 1:1000 adrenaline into the splenic artery, the splenic volume was reduced by 75%. In past years, when chloral hydrate was used as an anesthetic in cattle, a similar acute splenic congestion was seen at surgery.

Grossly the spleen is extremely enlarged ([Fig. 13-48](#)), and the cut surface is notably congested and bulges and oozes blood. The splenic capsule can be fragile and easily ruptured. Histologically, as a result of the distention of the red pulp by blood, the normal architecture of the splenic parenchyma is almost obliterated by masses of blood cells, chiefly erythrocytes ([Fig. 13-49](#)). The lymphoid tissues (periarteriolar lymphoid sheaths and splenic follicles) are widely separated and may be absent from the section examined. Because of the splenic distention, trabeculae and the capsule are thin.

Electric stunning of pigs at slaughter is occasionally associated with a large congested spleen.

13.2.2.2.2.1.2

#### Acute hyperemia.

In septicemias and bacteremias, microbes are transported to the splenic red pulp, where they are rapidly phagocytosed by the splenic macrophages. Enormous numbers of bacteria injected intravenously can be cleared from the blood in 20 to 30 minutes. The response of the spleen depends on the duration of the disease. In acutely fatal cases, such as anthrax and fulminating salmonellosis, distension by blood may be the only finding. If there is a longer interval before death, as in swine erysipelas and the less acute forms of salmonellosis, there may be time for neutrophils to accumulate and macrophages in the splenic red pulp to undergo hyperplasia.

810

## Pathologic Basis of Veterinary Disease, 4th Edition

---

In human medicine it has been generally accepted that acute sepsis (septicemia) can cause acute splenitis, loosely defined as splenomegaly, which is the result of acute splenic congestion and neutrophilic infiltrates. A retrospective study in human beings did not support this; in fact, there was little significant change in the spleen. However, in mice injected intraperitoneally with *Burkholderia mallei* (glanders bacillus), there was notable splenomegaly and histologically the spleen was infiltrated initially (within hours) with neutrophils and later (>24 hours) by pyogranulomatous inflammation. Although the Kupffer cells of the liver make up 80% to 90% of the body's macrophages in some animals, in these mice the greatest number of bacilli was present in the spleen.

Grossly in acute septicemias in domestic animals, the spleen is moderately enlarged and red from congestion, and the cut surface oozes blood.

13.2.2.2.1.2.1

### Anthrax.

Anthrax is caused by *Bacillus anthracis* and is primarily a disease of ruminants, especially cattle and sheep. *Bacillus anthracis* is a gram-positive, large rod-shaped, endospore-forming bacterium, which grows in an aerobic to facultative anaerobic environment. Ingested spores replicate locally in the intestinal tract, spread to regional lymph nodes, and then disseminate systemically, through the blood stream, resulting in septicemia. *Bacillus anthracis* produces exotoxins, which degrade endothelial cell membranes and enzyme systems. The spleen, in a case of anthrax, is uniformly enlarged, is dark red to bluish-black, and contains abundant unclotted blood because of extensive liquefactive necrosis. Impression smears of peripheral blood can contain gram-positive rod-shaped bacteria. Anthrax cases are not normally necropsied, as exposure to air causes the bacteria to sporulate and anthrax spores are extremely resistant and contaminate the environment.

13.2.2.2.1.3

### Acute hemolytic anemias.

In hemolytic diseases, such as acute babesiosis, and during the hemolytic crises in equine infectious anemia, because of the need to remove parasitized and altered erythrocytes from the circulation, the spleen is grossly enlarged and congested, and the cut surface oozes blood. If the condition becomes chronic, hyperplasia of the red pulp macrophages takes place, and because of the decreased numbers of parasitized erythrocytes to be phagocytosed, congestion is reduced.

13.2.2.2.2

### Uniform splenomegaly with a firm consistency—"meaty" spleen

Enlargement and firm consistency of the spleen is due to proliferation of cells, most frequently macrophages in the red pulp (Fig. 13-47, B). In fact, splenomegaly from an increased splenic phagocytosis could be considered a response to workload, a sort of "workload hyperplasia" in response to the need to phagocytose organisms in prolonged bacteremias or parasitemias from hemotropic organisms. Other causes are diffuse neoplasia, such as lymphoma, lymphoid hyperplasia, and advanced stages of some storage diseases.

The appearance of the cut surface will vary with the extent of the change in the red and white pulp. In the early stages, red pulp will have its normal color, but it will become paler as lesions become extensive.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The white pulp is not visible in normal spleens, but in cases of marked lymphoid hyperplasia, it may be visible on the cut surface as whitish foci, up to 1 to 2 mm in diameter, scattered through the red pulp. Moderately enlarged, firm spleens with visible white pulp are indicative of “reactive spleens,” or lymphoma (lymphosarcoma) (see Lymphoid Hyperplasia).

The common causes of uniform splenomegaly are listed in [Table 13-3](#) and include the following:

1. Bacteremias and low-grade septicemias
2. Chronic infectious diseases, usually granulomatous. A chronic infectious splenitis can be caused by bacteria or fungi. Many of the former produce chronic abscesses, which may be disseminated through the parenchyma or cause a single abscess (see Splenic Nodules).
3. Prolonged hemolytic anemias (such as canine immune-mediated hemolytic anemia)
4. Lymphoid hyperplasia—usually not sufficiently extensive to cause splenomegaly
5. Neoplasms, such as lymphoma (lymphosarcoma)
6. Stored or deposits of material, such as in storage diseases or amyloidosis
7. Extramedullary hematopoiesis as a response to anemia or found in the spleens of aging dogs; but this alone is usually not extensive enough to cause splenomegaly.
8. Splenic myeloid metaplasia, histiocytosis and hypersplenism in dogs

811

812

13.2.2.2.2.1

### Bacteremias and septicemias.

In animals, the most fulminating septicemias (e.g., anthrax) cause splenomegaly with marked congestion (see previous discussion). Less virulent bacteria, which do not result in a quick death but have a longer clinical course, cause hyperplasia of macrophages and accumulations of neutrophils in the spleen. Some of the more common bacteria that cause bacteremia and/or septicemia, include specific serotypes of *Escherichia coli* (septicemic colibacillosis); biotype A and biotype T of *Pasteurella multocida* (septicemic pasteurellosis); *Streptococcus* spp. (neonatal septicemia); *Listeria monocytogenes* (listeric septicemia); *Hemophilus agni* (*Hemophilus* septicemia), *Erysipelothrix rhusiopathiae* (septicemic erysipelas), and *Salmonella* spp. (septicemic salmonellosis).

13.2.2.2.2.2

### Chronic infectious diseases.

Chronic infectious splenic diseases can cause abscesses (see nodular spleen discussion later), but are commonly associated with uniformly enlarged firm spleens. Firm spleens in these diseases result from one or more of three processes:

1. Macrophage hyperplasia
2. Chronic granulomatosis diseases (granulomatous inflammation)
3. Lymphoid hyperplasia

## Pathologic Basis of Veterinary Disease, 4th Edition

13.2.2.2.2.2.1

### Macrophage hyperplasia.

Macrophage hyperplasia occurs chiefly in the red pulp to phagocytose organisms, bacteria, or parasitized erythrocytes. This process is particularly well exemplified in histoplasmosis and leishmaniasis. *Histoplasma capsulatum* causes a marked proliferation of cells of the monocyte-macrophage system, and the resultant accumulation of macrophages in the spleen may enlarge this organ to several times its normal size (Fig. 13-50). *Leishmania* spp. also cause proliferation of macrophages, and large areas of the spleen may be replaced by macrophages. These cells also infiltrate the bone marrow and portal areas of the liver.

13.2.2.2.2.2.2

### Chronic granulomatosis diseases.

These diseases occur: (1) in response to bacteria that are intracellular facultative pathogens of macrophages, which include but are not limited to mycobacteria (*Mycobacterium bovis*, tuberculosis), *Brucella* spp. (brucellosis), and *Francisella tularensis* (tularemia) (see Large Lymph Nodes); (2) in systemic mycoses (see Large Lymph Nodes) such as blastomycosis (*Blastomyces dermatitidis*). Some of these organisms may also produce nodular enlarged spleens from the formation of granulomas (see Splenic Nodules with Firm Consistency).

**Fig. 13-50 Histoplasmosis, spleen, dog. A,** There is uniform splenomegaly and the surface of the spleen is mottled from the diffuse granulomatous infiltrate. **B,** Cross section of spleen. The red pulp has been almost completely replaced by diffuse noncaseous granulomatous inflammation. (**A and B** Courtesy Department of Veterinary Biosciences, The Ohio State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

13.2.2.2.2.2.3

### Lymphoid hyperplasia.

Lymphoid hyperplasia, both follicular and of the PALS, are part of the response to blood-borne antigens, which enter the marginal zone and are presented by antigen-presenting cells to T lymphocytes and B lymphocytes, resulting in cell-mediated and humoral immunity. In chronic diseases, the marginal zone may be markedly enlarged.

13.2.2.2.2.3

### Prolonged hemolytic anemias.

Acute hemolytic anemias cause splenomegaly with congestion (bloody spleens), but if the hemolysis is less severe or more chronic, the spleen is firm and red but not as congested because fewer erythrocytes are being phagocytosed. Proliferation of these macrophages in the red pulp results in an enlarged, firm spleen. Because of extravascular hemolysis of the altered erythrocytes, the red pulp, in addition to being firm, may be red to dark red but does not ooze blood. Splenic enlargement in these diseases may also be partially due to hyperplasia of T- and B-lymphocyte areas. Acute hemolytic anemias are discussed in more detail earlier in this chapter.

812

813

13.2.2.2.2.3.1

### Equine infectious anemia.

Equine infectious anemia has cyclical periods of viremia, immunologically mediated damage to erythrocytes and platelets, and phagocytosis to remove altered erythrocytes and platelets. These cycles result in proliferation of red pulp macrophages, hyperplasia of hematopoietic cells (EMH) to replace those lost, and hyperplasia of the T- and B-lymphocyte areas.

13.2.2.2.2.4

### Lymphoid hyperplasia.

PALSs and splenic follicles become hyperplastic in response to chronic antigenic stimulation (Fig. 13-51). The change in the splenic follicle is similar to that which occurs in the lymphoid follicle. Many of the chronic diseases listed earlier cause lymphoid hyperplasia and proliferation of the macrophages of the red pulp. Lymphoid hyperplasia may also occur focally or regionally, at least in the canine spleen, in the absence of generalized antigenic stimulus. These areas are present grossly as nodular enlargements of the splenic parenchyma generally less than 8 mm in diameter and are often obscured by an associated hematoma. These are discussed in more detail later in the chapter (see Nodular Hyperplasia).

13.2.2.2.2.5

### Neoplasia

13.2.2.2.2.5.1

### Primary neoplasms.

Primary neoplastic diseases of the spleen arise from cell populations that normally exist in the spleen and include hematopoietic components such as lymphocytes and macrophages and stromal cells such as fibroblasts, smooth muscle, and endothelium. Primary splenic lymphoma, although rare, can produce a uniform splenomegaly (Fig. 13-52, A). Microscopically the normal white pulp follicles are displaced, and the red pulp is occupied to varying degrees by neoplastic lymphocytes (Fig. 13-52, B). (The different types of lymphoma in domestic animals are discussed under Hematopoietic Neoplasia.) In the advanced stages of disease, acute and chronic leukemias cause

## Pathologic Basis of Veterinary Disease, 4th Edition

---

uniform splenomegaly. The splenic red pulp appears hypercellular from the extensive infiltration of tumor cells. It should be appreciated that in some cases many of these different types of primary splenic neoplasms will produce nodular lesions discussed later.

**Fig. 13-51 Lymphoid hyperplasia, cross section of spleen, dog.**

Each of the 1- to 3-mm pale foci consists of hyperplastic periarteriolar lymphoid sheaths and splenic follicles. These structures are not visible in the normal spleen but become enlarged and visible from marked lymphoid hyperplasia or from lymphoma. (*Courtesy Dr. S. Wolpert, USDA/FSIS; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.*)

Fig. 13-52 **Lymphoma (lymphosarcoma).** **A**, Spleen and liver, dog. The spleen is grossly enlarged with pale subcapsular nodules. The mottled appearance of the liver is caused by infiltration of malignant lymphocytes into the portal areas. **B**, Spleen, cow. The pale horizontal band on the upper right is a trabeculum. The remainder of the spleen is diffusely infiltrated by malignant lymphocytes, which have completely obliterated all normal architecture. Note the absence of any normal red or white pulp. H&E stain. (**A** Courtesy College of Veterinary Medicine, University of Illinois. **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

13.2.2.2.2.5.2

### Metastatic neoplasms.

The spleen is not a common site of metastatic neoplasia, but when it occurs, it generally causes nodules—not uniform splenomegaly. Metastatic neoplasms of the spleen, which cause uniform splenomegaly, can originate from the same hematopoietic cell populations as those that cause primary neoplastic disease, but the neoplastic cells metastasize to the spleen hematogenously. Lymphoma is the most common metastatic neoplasm of the spleen.

813

814

13.2.2.2.2.6

### Stored deposits of material

13.2.2.2.2.6.1

### Lysosomal storage diseases.

Storage diseases constitute a large heterogeneous group of genetically determined and acquired disorders, which result from the lack of an enzyme required to facilitate the metabolism of a specific substrate. Storage diseases occur in animals less than 1 year of age. In general, these substrates are lipids and/or carbohydrates, which, due to lack of normal processing within lysosomes, accumulate in these cells. Major categories of stored materials include mucopolysaccharides, sphingolipids, lipids, glycoproteins, glycogen, and mucolipids. Macrophages within the spleen are unable to degrade these substrates and essentially serve to store them in an unprocessed form. Ultimately the mass of this undigested substrate results in a uniformly enlarged firm spleen, which may be pale red, depending on the amount of unprocessed lipid or carbohydrate that has accumulated.

13.2.2.2.2.6.2

### Amyloid.

The accumulation of amyloid in the spleen may occur with primary (AL) or secondary (AA) amyloidosis (see [Chapters 1](#) and [5](#)). Rarely can this accumulation be so severe as to cause uniform splenomegaly ([Fig. 13-53](#)), in which the spleen is firm, rubbery to waxy, and beige to orange.

13.2.2.2.2.7

### Extramedullary hematopoiesis (EMH).

Hormonal or physiologic signaling mechanisms within the spleen initiate the synthesis of progenitor cells from stem cells in an attempt to fulfill the cellular demands of the systemic circulation. However, splenic EMH is often found incidentally, and many consider its presence in the spleen to be within normal limits, at least in dogs. It usually involves cells of the erythroid, myeloid, and megakaryocytes lines, but one type usually predominates. Splenic enlargement from extramedullary hematopoiesis may be minimal, and EMH is often not detectable on gross examination. Extramedullary hematopoiesis may occur in cases of chronic anemia and in conditions such as chronic respiratory disease or chronic cardiovascular disease, in which the circulation is not able to adequately maintain systemic  $pO_2$  concentrations. Extramedullary myelopoiesis may occur in suppurative bacterial diseases such as canine pyometra, in which there is an excessive demand for neutrophils that exceeds the supply from the bone marrow.

Fig. 13-53 **Amyloid spleen, dog.** The spleen is pale beige, firm and waxy, and uniformly distended in this advanced case of amyloidosis. (*Courtesy College of Veterinary Medicine, University of Illinois.*)

EMH is also present in splenic nodular hyperplasia.

13.2.2.2.2.8

### Splenic myeloid metaplasia, histiocytosis, and hypersplenism in the dog.

This disease has been described recently and is characterized by severe, diffuse, and persistent splenomegaly, and the splenic capsule may be smooth or have multiple and confluent nodules. There is often random vascular thrombosis, producing grossly visible splenic infarcts. Microscopically, extramedullary hematopoiesis is present with interspersed foci of prominent macrophages (periarteriolar macrophage sheaths [PAMSs]). The process effaces the splenic red pulp and is responsible for the splenic enlargement. This disease may be rather benign, not involving other organs, in which case splenectomy is generally curative. However, EMH may be systemic, involving bone marrow and liver, and this is indicative of a poor prognosis.

13.2.2.2.2.3

### Splenic nodules with a bloody consistency

The most common diseases or conditions resulting in nodular splenomegaly with bloody consistency are: (1) hematomas induced by lymphoid hyperplastic nodules; (2) hematomas induced by splenic vascular neoplasms; (3) incompletely contracted areas of the spleen; (4) vascular neoplasms (hemangiomas and hemangiosarcomas); and (5) acute splenic infarcts. The term *nodule* has been

## Pathologic Basis of Veterinary Disease, 4th Edition

---

applied rather loosely here. In some of these conditions, such as incompletely contracted areas of the spleen, the elevated area of the spleen is not as well defined as the term *nodule* would imply.

13.2.2.2.3.1

### Hematomas (induced by lymphoid hyperplastic nodules).

Hematomas in the spleen are usually associated with hyperplastic lymphoid nodules (arising from the PALS of the white pulp) and occur regionally or focally in the splenic parenchyma. These nodules arise idiosyncratically in the canine and (less commonly) feline spleens and do not appear to be associated with general antigenic stimulation. Because the circulation in the marginal zone of the white pulp in these two species appears to be “open,” the blood exits via open-ended arterial capillaries to percolate among lymphocytes of the marginal zone and reenters through similar open venous capillaries. Distortion of this marginal zone area by hyperplastic lymphocytes disrupts the normal blood flow, resulting in accumulation of pooled blood that is unable to find its way into sinusoids or red pulp vascular spaces (reticular meshwork), thus forming a hematoma that further distorts the splenic architecture.

814

815

13.2.2.2.3.2

### Hematomas (induced by splenic vascular neoplasms).

Hematomas can also occur secondarily to splenic neoplasms of vascular origin. Bleeding into the red pulp, which is confined by the splenic capsule, produces a red to dark red soft bulging, usually solitary mass of varying size (2 to 15 cm in diameter) (Fig. 13-54). If the capsule over the hematoma ruptures, hemoperitoneum, hypovolemic shock, circulatory failure, and death can ensue. Splenic hematomas progress through a reparative process in which the blood coagulates and, over days, breaks down into a dark red brown soft mass (Fig. 13-55, A). The clotted blood is infiltrated by macrophages, which phagocytose erythrocytes and break down hemoglobin initially with the formation of bilirubin and later hemosiderin (Fig. 13-55, B). Newly formed capillaries (neovascularization) infiltrate the lesion and fill the site with granulation tissue, which matures to collagen. Collagenous septa divide the clotted blood into distinct “compartments” of varying sizes. The blood eventually liquefies and is phagocytosed and replaced by a scar. In the late stage, histologically the area contains scar tissue and intracellular and extracellular deposits of hemosiderin.

815

816

Fig. 13-54 **Hematoma, spleen, dog.** The ventral extremity of the spleen has a large hematoma on its visceral surface. Note the two nodules of splenic hyperplasia (*dorsal extremity*), a common site for hematomas to occur ([Fig. 13-59](#)). (Courtesy College of Veterinary Medicine, University of Illinois.)

Fig. 13-55 **Subcapsular hematoma, spleen, dog.** **A**, Note the separation of the splenic capsule from the underlying parenchyma by a mass of blood. **B**, The yellow material is bilirubin, resulting from the breakdown of erythrocytes in a subcapsular hemorrhage. H&E stain. (**A and B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

13.2.2.2.2.3.3

### Incompletely contracted areas of the spleen.

Acute splenic infarcts can be indistinguishable from areas of incompletely contracted splenic parenchyma. Contraction can occur during circulatory (hypovolemic, cardiogenic, or septic) shock or be a parasympathetic response, as in flight or fright situations. Incompletely contracted areas appear as numerous dark red to black, raised, soft, blood-filled areas of various sizes. These are usually at the margins of the spleen, and the intervening areas are depressed and red. The latter areas are normal, contracted splenic red pulp devoid of blood. Incompletely contracted areas were previously confused with splenic infarcts and sometimes hematomas, but they are now recognized to be caused by failure of smooth muscle in some areas to contract, resulting in incomplete splenic evacuation of stored blood.

### 13.2.2.2.3.4

#### Vascular neoplasms.

The most common cause of nodular splenomegaly associated with a bloody (congested) spleen is neoplasms of vascular endothelial cell origin. Both benign (hemangioma) and malignant (hemangiosarcoma) forms commonly occur.

Grossly, hemangiomas are usually solitary masses, dark red to bluish-purple, friable, and usually covered by a thin shiny serosa. There are no metastases to the liver or peritoneal mesothelium. Hemangiomas are composed of well-differentiated endothelial cells, which differentiate into relatively well-formed vascular spaces. Grossly, hemangiosarcomas can be difficult to differentiate from hemangiomas and hematomas. They are dark red to bluish-purple, friable, and usually covered by a thin serosa (Fig. 13-56), and they commonly occur as numerous large, discrete, and coalescing masses, scattered randomly throughout the spleen and effacing normal splenic architecture. They also may give rise to hepatic, pulmonary, and/or peritoneal metastases, the latter usually occurring by seeding the peritoneal cavity. Hemangiosarcomas are composed of anaplastic endothelial cells, which form haphazardly arranged and poorly defined vascular spaces (Fig. 13-57) that most often contain liquid (nonclotted) blood.

Splenic hemangiosarcomas can occur as primary masses that arise within the spleen or as metastases from distant sites, including skin or right atrium. Primary splenic hemangiosarcomas metastasize to the liver early and frequently; therefore evaluation of the abdomen must include a detailed examination of the entire abdominal cavity for hepatic and peritoneal metastases. Splenic hemangiosarcomas have a poor prognosis.

### 13.2.2.2.3.5

#### Acute splenic infarcts.

Splenic infarcts occur principally in: (1) the subcapsular areas of the spleen because of poor perfusion and reduced venous return and (2) in areas of acute vascular occlusion or vasculitis induced by infectious agents. Acute splenic infarcts, which are initially hemorrhagic, are not always clearly visible in the early stages but appear as discrete, deeply congested areas with focal capsular distention. As the lesion develops, it becomes somewhat wedge-shaped and gray-white with the base at the splenic capsule (Fig. 13-58). Later a scar forms. Spleens distended with blood are prone to thrombosis and infarction.

816

817

Fig. 13-58 Chronic splenic infarct, spleen, dog. Note the characteristic pale, wedge-shaped area with its base against the capsule of the spleen. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

13.2.2.2.4

### Splenic nodules with a firm consistency

The most common diseases or conditions associated with firm-consistency splenic nodules are: (1) nodular hyperplasia, (2) primary neoplasms, (3) metastatic neoplasms, (4) granulomas, and (5) abscesses.

### Nodular hyperplasia.

Splenic nodular hyperplasia is most commonly seen in the spleen of older dogs and is often an incidental finding. This lesion has also been called canine nodular splenic hyperplasia and splenoma. Nodules are formed by hyperplastic lymphoid cells or mixed accumulations of hyperplastic erythroid, myeloid, and megakaryocytic cells (EMH) with lymphoid cells. They can appear as single discrete or multiple coalescing firm nodules protruding from the surface but covered by the splenic capsule. The capsular surfaces and cut surfaces often have a mottled red-white pattern because of the intermingling of erythrocytes and hyperplastic leukocytes. Hyperplastic nodules are usually hemispherical and up to 2 cm or larger in diameter (Fig. 13-59). They have no deleterious effect unless they result in a large hematoma, which can rupture and cause hemoperitoneum. Rupture is usually because of trauma or even from a misjudged jump from a couch. These masses must be distinguished from other types of nodules in the spleen, including those of hematoma, hemangioma, hemangiosarcoma, and primary or metastatic neoplasms.

Fig. 13-59 Nodular hyperplasia, spleen, dog. **A**, A hemispherical 4-cm diameter nodule is protruding from the capsular surface. **B**, Cross section of the nodular mass showing intermixed red and white areas composed of red blood cells and proliferating leukocytes. (**A**, Courtesy College of Veterinary Medicine, University of Illinois. **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

13.2.2.2.4.2

### Primary neoplasms.

The primary neoplastic diseases of the spleen that result in nodular enlarged firm spleens include lymphoma, fibroma, fibrosarcoma, osteosarcoma, myxosarcoma, histiocytic sarcoma, myelolipoma, lipoma, liposarcoma, leiomyoma, and leiomyosarcoma. These neoplasms may be solitary or multiple and are locally extensive. They are firm, are raised above the capsular surface but usually confined by the capsular surface, and bulge from the cut surface. Because of the cell of origin (mesenchymal-spindle cells [fibroblasts, myocytes]), the cut surface of these spindle cell neoplasms may have a fibrillar appearance. Myxosarcomas have a distinctively mucinous or slimy character to the cut surface.

817

818

Malignant fibrous histiocytomas in canine spleens are considered a continuum of proliferations of fibrous and histiocytic cells (fibrohistiocytic nodule) normally found in the splenic reticular meshwork of the red pulp. They are most often seen as fibrous and histiocytic cellular proliferations in association with hyperplastic lymphoid cells. As the ratio of fibrohistiocytic cells to lymphoid cells increases, the malignant potential of the nodules also increases. Grossly these tumors are often homogeneous, are white, and bulge from the cut surface of the spleen. To our knowledge, there is no evidence that malignant fibrous histiocytoma of the canine spleen is derived from the same cell of origin as the soft-tissue sarcoma of the same name (occasionally called giant cell tumor of soft parts) that occurs in dogs and cats.

Myelolipomas (neoplasms composed of approximately equal quantities of hematopoietic cells and adipose tissue) also may form nodules in the spleen, and these are softer than other mesenchymal-spindle cell neoplasms. Similarly, benign tumors of adipocytes (lipomas) can occur as a single neoplasm and cause splenomegaly.

In cats, the most common neoplasms (primary and secondary) forming nodules in the spleen are, in descending order of frequency, mast cell tumor, lymphoma (lymphosarcoma), myeloid neoplasms, and hemangiosarcomas.

13.2.2.2.4.3

### Metastatic neoplasms.

Metastatic neoplastic diseases of the spleen that result in enlarged nodular firm spleens can arise from hematopoietic stem cells, from mesenchymal (sarcomas) cell lines, or epithelial (carcinomas) cell lines. These neoplasms may be solitary or multiple and highly invasive and can involve large areas of the spleen. They are firm nodular masses, usually confined by the capsule, and may bulge from the cut surface. Metastatic neoplasms of hematopoietic origin may be lymphoid or myeloid (see Hematopoietic Neoplasia).

Metastatic neoplasms of mesenchymal (sarcomas) origin include fibrosarcomas, leiomyosarcomas, and osteosarcomas. The cut surface of mesenchymal neoplasms may have a fibrillar appearance, which can be difficult to cut if osteoid and/or mineralized bone is present. Metastatic neoplasms of epithelial (carcinomas) origin include most of the common carcinomas (mammary, prostatic, lung) and carcinoids (chemodectomas). The cut surface of epithelial neoplasms may have a lobulated bulging appearance (Fig. 13-60). Malignant melanomas may be black.

Fig. 13-60 **Metastatic carcinoma, spleen, ox.** The white mass is an undifferentiated carcinoma, which has metastasized to the spleen. ## Pathologic Basis of Veterinary Disease, 4th Edition

13.2.2.2.4.4

### Granulomas (chronic infectious diseases).

Some of the microorganisms listed earlier as causing diffuse granulomatous splenitis and uniform splenomegaly can also cause focal lesions. Others organisms, such as *Brucella abortus* and *Mycobacterium bovis*, cause focal granulomas and nodules in the spleens of pigs. Porcine circovirus 2 causes multifocal noncaseous granulomas with giant cells in the red pulp without splenomegaly.

818

819

**Fig. 13-62 Chronic multifocal suppurative splenitis, splenic abscesses, *Arcanobacterium pyogenes*, spleen, cow.** Multiple encapsulated abscesses are present throughout the parenchyma of the spleen, the result of a previous bacteremia. (Courtesy Department of Veterinary Biosciences, The Ohio State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

13.2.2.2.4.5

### Abscesses (acute infectious diseases).

Abscesses in the spleen (multifocal chronic suppurative splenitis) are relatively rare but can develop following septicemia and/or bacteremia, usually from pyogenic bacteria such as *Streptococcus* spp., *Rhodococcus equi* (Fig. 13-61), *Arcanobacterium pyogenes* (Fig. 13-62), and *Corynebacterium pseudotuberculosis*. The bacteria are filtered by the monocyte-macrophage system in the spleen but are not killed and replicate within the splenic red pulp to form abscesses of varied sizes, composition, and consistency. Abscesses will bulge from the capsule of the spleen or from cut surfaces. The exudate can vary in texture and color depending on the inciting organism. In most cases, the content is white to yellow-white and moderately thick, and with time becomes encapsulated.

Although there are a large number of diseases and conditions commonly associated with bacteremia, including navel ill, joint ill, chronic respiratory infections, bacterial endocarditis, chronic skin

## Pathologic Basis of Veterinary Disease, 4th Edition

---

diseases, castration, tail docking, and ear trimming and/or notching, these rarely result in visible splenic abscesses. *Streptococcus equi* ssp. *equi*, the cause of equine strangles, is the prototypical bacterium of acute bacterial infections. The classic lesion of strangles is a nasopharyngitis with lymphadenitis of the regional lymph nodes, usually the mandibular and retropharyngeal. If the organism becomes bacteremic, it commonly causes abscesses in liver, kidney, synovial structures, mesenteric and mediastinal lymph nodes, and occasionally in the spleen. Bastard strangles is the term given to the form of the disease characterized by *Streptococcus equi* ssp. *equi* abscesses anywhere in the body other than the pharyngeal area.

In bovine traumatic reticuloperitonitis, splenic abscesses can result from a direct extension of peritonitis from a penetrating foreign body from the reticulum (see Spleen and Portals of Entry sections). In horses, *Gasterophilus* and *Habronema* spp. can cause gastric ulcers that lead to perforation of the stomach wall and the formation of abscesses in the adjacent spleen.

13.2.2.2.2.5

### Small spleens

The most common diseases or conditions associated with small spleens are: (1) developmental anomalies, (2) aging changes, (3) wasting and/or cachectic diseases, and (4) splenic contraction.

13.2.2.2.2.5.1

#### Developmental diseases.

Immunodeficiency diseases can result in small spleens, as well as small thymuses and lymph nodes. They occur most commonly as primary immunodeficiency diseases of young animals and involve defects in T or B lymphocytes or a combination. Severe combined immunodeficiency (SCID) in Arabian foals is a hereditary disease in which affected foals lack T and B lymphocytes and therefore is characterized by notable lymphoid hypoplasia of primary and secondary lymphoid tissues (Fig. 13-43). Grossly, these spleens are exceptionally small, firm, and pale red. Spleens from affected animals lack lymphoid follicles and PALS, and there are few to no plasma cells. SCID also occurs in the dog, and although the molecular basis is different from that in the horse, the pathologic features of lymphoid tissues are similar. These diseases and their pathologic findings are discussed in Chapter 5.

Accessory spleens can be either congenital or acquired. Congenital accessory spleens are usually small and located in the gastrosplenic ligament. Following rupture of the spleen from injury in dogs, fragments of spleen may be implanted onto peritoneal surfaces. Here they become vascularized and functional. Implanted fragments grossly and histologically resemble normal splenic tissue. They have red and white pulp areas and a thick fibromuscular capsule. These features are important in differentiating accessory spleens from peritoneal implanted fragments (metastases) of hemangiosarcoma, which have a thin shiny serosal covering and a poor prognosis.

13.2.2.2.2.5.2

#### Aging changes.

The most notable aging change resulting in a small spleen is lymphoid atrophy, the result of loss of T lymphocytes and B lymphocytes.

Grossly the organ is small and the capsule may be wrinkled. Microscopically there is reduction in the white pulp; both PALSs and splenic follicles may be undetectable, and if present, follicles lack

## Pathologic Basis of Veterinary Disease, 4th Edition

---

germinal centers. Sinuses also lack blood, possibly because of anemia, and are collapsed—resulting in a condensation of their walls, which makes them appear fibrous.

13.2.2.2.5.3

### Wasting/cachectic diseases.

Any chronic disease, such as starvation, systemic neoplasia, and malabsorption syndrome, may produce cachexia. Starvation, although having a marked effect on the thymus with resultant atrophy of the T-lymphocyte areas in the spleen and lymph nodes, has little or no effect on the B-lymphocyte areas.

819

820

13.2.2.2.5.4

### Splenic contraction.

Contraction of the spleen is due to contraction of the smooth muscle in the capsule and trabeculae of storage and intermediate type spleens. It can be induced by the activation of the autonomic system and catecholamine release, which can occur in “fight or flight” situations, and in heart failure and cardiogenic, hypovolemic, and septic shock. It is also present in acute splenic rupture that has resulted in hemorrhage (hemoperitoneum). The contracted spleen is small, its surface is wrinkled, and the cut surface is dry.

13.2.2.2.3

### Miscellaneous Disorders of the Spleen

13.2.2.2.3.1

#### Hemosiderosis

Hemosiderin is a form of storage iron derived from the breakdown of erythrocytes, which normally occurs in the spleen. Thus some splenic hemosiderin is to be expected, and the amount varies with the species. It is most extensive in the horse. Excessive amounts of splenic hemosiderin are seen either from a reduced rate of erythropoiesis (less demand for iron) or from rapid destruction of erythrocytes, as in hemolytic anemias (increased stores of iron) such as those caused by immune hemolytic anemias or by hemotropic parasites. Excess hemosiderin may also occur in chronic heart failure and from the injection of iron dextran in pigs. Focal accumulations of hemosiderin in the capsule or parenchyma can be a sequela to hemorrhage, for example from trauma. Intraparenchymal deposits can also be sequelae to hematomas and infarcts. Hemosiderin is also present in siderocalcific plaques (see next section).

**Fig. 13-63 Sidero-calcific plaque, spleen, dog.** **A**, Multiple, sometimes confluent raised yellow-white plaquelike foci (sidero-calcific plaques) are present on the capsular surface of the body of the spleen. Note the nodular hyperplasia (incised). **B**, The sidero-calcific plaque lies in the fibrous connective tissue of the capsule and consists chiefly of calcium (blue) and hemosiderin (brown) in fibrous connective tissue. The yellow material is bilirubin, resulting from the breakdown of erythrocytes in a capsular hemorrhage. H&E stain. (**A** Courtesy College of Veterinary Medicine, University of Illinois. **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

13.2.2.2.3.2

### Sidero-calcific plaques

Sidero-calcific plaques are also known as Gamna-Gandy bodies. Grossly they are whitish to yellowish, hard, dry encrustations on the capsule. Usually they are most extensive along the margins of the spleen but can be elsewhere on the capsule (Fig. 13-63, A) and sometimes in the parenchyma. Microscopically they are frequently multicolored in an H&E stained section: yellow (bilirubin in early cases), golden brown (hemosiderin), and blue (calcium stained by hematoxylin) (Fig. 13-63, B). As they are often present in older dogs, they have been classified as a senile change, but they may be sequelae to previous hemorrhages.

13.2.2.2.3.3

### Splenic rupture

Splenic rupture is not infrequent in dogs and is most commonly from trauma, such as from an automobile accident. Thinning of the capsule can render the spleen more susceptible, and this occurs in splenomegaly at sites of hematomas and infarcts and over tumors such as hemangiomas, hemangiosarcomas, and malignant lymphoma.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

On gross examination, in acute cases, the spleen is markedly contracted with a wrinkled surface (Fig. 13-64). The rupture site can be a tear in the capsule, or the spleen can be broken into two or more pieces. Small pieces of splenic parenchyma may be scattered on the peritoneum (sometimes called “splattered spleen syndrome”). Clotted blood may adhere to the surface at the rupture site. If the rupture is not fatal, the spleen heals by scarring. At necropsy, there may be a capsular scar or two or more separate pieces of spleen adjacent to each other in the gastrosplenic ligament, and/or small accessory “spleens” in the peritoneum (Fig. 13-65). Exactly how functional these “spleens” are is questionable. They have erythrophagocytosis and are presumed to be capable of removing senescent erythrocytes, but as most of them are supplied by small arteries, and thus have limited blood supply, they are not likely to be effective in filtering bacteria out of the body's blood. Also, it is generally considered that at least half of the original splenic mass is required for protection against blood-borne bacterial infections. See previous accessory spleen discussion.

820

821

**Fig. 13-64 Acute splenic rupture and hemorrhage, spleen, dog.** The spleen has been almost transected by trauma. Because of the loss of blood, the spleen has contracted, the surface is crinkled, and the exposed surface of the parenchyma is dry. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

13.2.2.2.3.4

### Splenic fissures

Fissures in the splenic capsule are elongated grooves whose axes run parallel to the borders of the spleen. This developmental defect is seen mostly commonly in horses but also occurs in other animals. The surface of the fissure is smooth and covered by the normal splenic capsule.

**Fig. 13-65 Multiple “spleens,” dog.** The spleen had been broken into several parts, and the rupture sites have healed. These small pieces of spleen, sometimes referred to as daughter spleens, are functional but not very effective in filtration because of their relatively paltry blood supply. (*Courtesy Dr. H.B. Gelberg, College of Veterinary Medicine, Oregon State University.*)

13.2.2.2.3.5

### Chronic splenic infarcts

As in the early stage, chronic splenic infarcts are hemorrhagic and may elevate the capsule. They were discussed previously under Splenic Nodules with a Bloody Consistency. However, as the lesions age, they will diminish in size, become fibrosed, and may be depressed below the level of the adjacent capsule.

13.2.2.2.3.6

### Cysts

Occasionally, cystic nodules can be present within the spleen. These cysts are formed by intermediate stages of *Echinococcus granulosa* and *Cysticercus tenuicollis* and are seen most commonly in wild animal species.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 13.2.2.3 DISORDERS OF LYMPH NODES

Many of the inherited immunodeficiency diseases affecting the thymus and spleen cause similar lesions in the lymph nodes—lack of B lymphocytes or T lymphocytes, or both. Congenital hereditary lymphedema has been reported in certain breeds of cattle and dogs. Grossly the most severely affected animals have generalized subcutaneous edema (see [Fig. 2-13](#)) and fluid in the serous cavities and are stillborn. Histologically, in severe cases, lymphatics are aplastic, and peripheral and central lymph nodes are hypoplastic. Because at necropsy the pathologist has to evaluate the size of lymph nodes, disorders will be discussed on that basis.

#### 13.2.2.3.1 Small Lymph Nodes

The most common diseases or conditions associated with small lymph nodes are as follows:

1. Developmental disorders
2. Lack of antigenic stimulation
3. Cachexia and malnutrition
4. Aging
5. Viral infections

821

822

#### 13.2.2.3.1.1 Developmental disorders

##### 13.2.2.3.1.1.1 Hypoplasia, immunodeficiency syndromes.

Neonatal animals with primary immunodeficiency diseases of either B lymphocytes or T lymphocytes, or both, often have extremely small to undetectable lymph nodes. In SCID dogs and horses, lymphoid tissues including lymph nodes from affected animals are characterized by an absence of lymphoid follicles and corticomedullary differentiation, and there are few to no lymphocytes and plasma cells.

#### 13.2.2.3.1.2 Lack of antigenic stimulation

Size and components of the lymph node depend on whether it is “resting” or whether it is actively phagocytosing foreign material and/or responding to antigenic stimulation. In specific pathogen-free animals, the lymph nodes are small because they have not been antigenically stimulated. Histologically, there is a small number of primary lymphoid follicles and few or no secondary follicles. This can also be true of peripheral lymph nodes, such as the popliteal, of normal neonatal animals. However, those lymph nodes constantly receiving antigenic material and perhaps bacteria, such as lymph nodes draining the gut, will be large, with active lymphoid follicles containing germinal centers.

It is also important to realize that the immunologic response of a lymph node may be short-lived. After an initial antigenic stimulus, primary lymphoid follicles develop into secondary lymphoid follicles with characteristic germinal centers and produce immunoblasts, which mature into plasma cells and migrate

## Pathologic Basis of Veterinary Disease, 4th Edition

---

to the medullary cords. Continued stimulation will result in the formation of more primary and secondary lymphoid follicles (follicular hyperplasia). When active, their germinal centers will have many cells undergoing mitosis. Later, as the antigenic response wanes or as the result of long continued stimulation, germinal centers will become depleted of lymphocytes and mitotic figures will be absent. This appearance is described as “depleted germinal centers” or as “reactive depleted lymphoid follicles.” Thus lymph nodes may be small because they have never been stimulated (e.g., a peripheral lymph node, such as the popliteal, in a neonatal animal) or because the lymph node has regressed after the cessation of an antigenic stimulus. Thus neither lymphoid follicles, nor germinal centers, are permanent structures. The number of follicles increases or decreases with changes in the intensity of the antigenic stimuli, and the germinal centers go through a cycle of activation, depletion, and rest as described previously.

13.2.2.3.1.3

### Cachexia and malnutrition

Any chronic disease such as starvation, systemic neoplasia, and malabsorption syndrome will ultimately produce cachexia. As described under Inflammatory and Degenerative Disorders and Wasting/Cachectic Diseases, starvation mainly reduces the production of T lymphocytes, causing atrophy of the T-lymphocyte areas but having little or no effect on the B-lymphocyte areas.

13.2.2.3.1.4

### Aging

Aging results in a depression of the immune system, and as a result, lymph nodes are small. The cortex is reduced, there is a loss of B lymphocytes and T lymphocytes, and lymphoid follicles may be absent.

13.2.2.3.1.5

### Viral infections

Many viral infections of human beings and animals target lymphocytes and cause the destruction of lymphoid tissue. In BVD, in the mesenteric lymph nodes, there is a reduction in the number of lymphocytes and necrosis of the germinal centers. Canine distemper virus preferentially infects lymphoid, epithelial, and nervous cells. The distemper virus spreads from the tonsil and tracheobronchial lymph nodes to the spleen, bone marrow, and distant lymph nodes, where it causes lymphoid necrosis. The cortices of lymph nodes of dogs infected with canine distemper are depleted of lymphocytes 6 to 9 days after exposure. This loss of lymphocytes is also reflected hematologically, and affected dogs develop a profound lymphopenia. Although some viruses destroy lymphoid tissue, others can stimulate lymphoid tissue (e.g., Aleutian mink disease virus, maedi-visna virus, and malignant catarrhal fever virus) or cause neoplasia (e.g., feline leukemia virus, bovine leukemia virus, and Marek's disease). Inclusion bodies, typical of porcine inclusion body rhinitis, are found in other epithelia and in lymph nodes, presumably as the result of a viremia.

13.2.2.3.2

### Large Lymph Nodes

Causes of enlarged lymph nodes are as follows:

1. Follicular (B-lymphocyte) and diffuse (T-lymphocyte) lymphoid hyperplasia
2. Lymphadenitis—acute

## Pathologic Basis of Veterinary Disease, 4th Edition

---

3. Lymphadenitis—chronic, including encapsulated abscesses; granulomatous inflammation; diffuse or focal
4. Primary neoplasms
5. Metastatic neoplasms
6. Hyperplasia of the monocyte-macrophage system

13.2.2.3.2.1

### Lymphoid hyperplasia

Follicular lymphoid hyperplasia can involve large numbers of lymph nodes, as in a systemic disease, or can be localized to a regional lymph node draining an inflamed area. It is thus a common response, provided the animal survives for several days or longer. Follicular lymphoid hyperplasia can be present in the initial stages of a disease, but this may be followed by loss of lymphocytes from the follicles from lymphocytolysis as in many viral diseases (e.g., EHV-1). With time, the lymph follicles become “exhausted,” and active proliferation in the germinal centers ceases.

822

823

Follicular lymphoid hyperplasia is evident in any regional lymph node draining an area in which there are inflammatory products or antigens (e.g., tuberculin from a tuberculin test or an injected vaccine). It is also particularly notable in lymph nodes draining areas of chronic inflammation (e.g., mammary lymph nodes in chronic bovine mastitis). Follicular lymphoid hyperplasia is characterized by proliferation of lymphoid follicles (Fig. 13-66), which have active germinal centers to produce plasma cells to secrete antibody and an increase in T lymphocytes in the paracortical areas. In acute inflammation, these changes commence after several days.

Grossly, when there is notable lymphoid hyperplasia, lymph nodes will be enlarged, the capsule may be tense, and on incision the parenchyma will bulge. The cortex may be increased in width.

Microscopically, lymph nodes are enlarged chiefly because of the expansion of the cortex by increased numbers of lymphoid follicles (follicular lymphoid hyperplasia), most of which will have active germinal centers with numerous mitotic figures. Plasma cells precursors are generated here and then migrate to the medullary cords where they develop into antibody secreting plasma cells. After about 10 days or more, secondary lymphoid follicles can become depleted of mitotically active cells and lymphocytes. The result is pale germinal centers consisting primarily of stromal and precursor cells. Medullary cords originally densely packed with plasma cells also become depleted, approximately a couple of weeks after the antigenic stimulus ceases.

**Fig. 13-66 Follicular lymphoid hyperplasia, chronic demodicosis, caudal cervical (prescapular) lymph node, dog.** The number of lymphoid follicles has increased (hyperplasia), and all of these have germinal centers (secondary follicles) indicating active proliferation of B lymphocytes to form plasma cells in response to an antigenic stimulus. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

### 13.2.2.3.2.2

#### Acute lymphadenitis

Acute lymphadenitis is usually the result of a regional lymph node draining an inflammatory site and becoming infected (e.g., the medial retropharyngeal lymph nodes in acute rhinitis, tracheobronchial lymph nodes in pneumonia [Fig. 13-67], and the supramammary [mammary] lymph node in mastitis). In some instances, lymphadenitis may be accompanied by inflammation of the afferent lymphatics (lymphangitis). The material draining to the regional lymph node may be bacteria, inflammatory products including mediators, or a sterile irritant. Examination of these lymph nodes should include culturing for bacteria, examination of smears, and histologic sections for bacteria and fungi.

Grossly, lymph nodes are enlarged and may be soft or firm, depending on the amount of exudate. The cut surface may be reddened both from local hyperemia and from blood draining from an inflammatory site. When incised, the parenchyma may bulge, and the surface may be wet with blood, lymph, or pus.

823

Suppuration is usually the result of pyogenic bacteria (*Streptococcus equi* ssp. *equi*, horses; *Streptococcus porcinus*, pig; and *Arcanobacterium pyogenes* in cattle and sheep). Microscopically the lymph node is hyperemic. In the initial stages, neutrophils and usually erythrocytes are present in the sinuses, which are distended with lymph or exudate. After the passage of a day or so, numerous macrophages enter the sinuses (sinus histiocytosis), particularly the medullary sinuses (Fig. 13-68).

824

Fig. 13-67 **Acute lymphadenitis, tracheobronchial lymph nodes, pig.**  
The nodes are enlarged and reddened from draining the pneumonic cranial lung lobes. Note the red consolidation of the dorsal portion of the cranial lung lobes. (*Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

**Fig. 13-68 Acute lymphadenitis (early), medulla of lymph node, dog.** Medullary sinus with adjacent medullary cords. The lumen of the medullary sinus contains numerous macrophages (large cells, sinus histiocytosis) and a few neutrophils. This is the type of early response seen when a lymph node drains an inflamed area. The medullary cords are packed with lymphocytes and some plasma cells. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

In equine strangles caused by *Streptococcus equi* ssp. *equi* and in porcine jowl abscess caused by *Streptococcus porcinus* (Fig. 13-69), the mandibular lymph nodes may rupture and discharge the pus to the surface of the skin. The pathogenesis is similar in both cases. In jowl abscess, *Streptococcus porcinus* colonizes the oral cavity, which results in infection of the tonsils and the regional lymph nodes. The mandibular lymph nodes are the most often affected, but the retropharyngeal and parotid lymph nodes may be involved. Multiple abscesses 1 to 10 cm in diameter may be present in the lymph nodes.

In equine strangles, the etiologic agent *Streptococcus equi* ssp. *equi* causes inflammation of the upper respiratory tract, which results in abscesses in the regional lymph nodes; usually the mandibular and retropharyngeal lymph nodes are most severely affected (Fig. 13-70). Ultimately the abscess may rupture and discharge the pus through a sinus to the surface.

Toxoplasmosis and salmonellosis both cause focal areas of necrosis in infected lymph nodes.

Fig. 13-69 **Jowl abscess, pig.** The submandibular swelling is caused by marked enlargement of the mandibular lymph nodes from a suppurative lymphadenitis caused by *Streptococcus porcinus*. (Courtesy Dr. J.M. King, College of Veterinary Medicine, Cornell University.)

Fig. 13-70 Acute suppurative lymphadenitis, equine strangles (*Streptococcus equi* ssp. *equi*), dorsal view of larynx, left and right retropharyngeal lymph nodes, horse. The lymph nodes are grossly distended with pus. (Courtesy College of Veterinary Medicine, University of Illinois.)

If inflammation in the lymph node continues for several days or longer, it will also be enlarged by the response of the immune system, which includes follicular hyperplasia, active germinal centers, and plasma cells in the medullary cords.

824

### 13.2.2.3.2.3

#### Chronic lymphadenitis

825

Chronic lymphadenitis may be a chronic suppurative (active) lymphadenitis with abscess formation, as in ovine caseous lymphadenitis; granulomatous; diffuse or focal; or a mixture of follicular lymphoid hyperplasia, plasmacytosis, fibrosis, sinus histiocytosis, and microabscesses. In the initial stages, the lymph node may not be notably enlarged. With chronic suppurative inflammation, abscesses range in size from small—causing no increase in the size of the lymph node—to large, even large enough to occupy the whole lymph node.

Granulomatous lymphadenitis may be focal as in tuberculosis, focal coalescing as in blastomycosis and cryptococcosis, or diffuse as in histoplasmosis.

### 13.2.2.3.2.3.1

#### Chronic suppurative lymphadenitis. (encapsulated abscesses).

The classic example of chronic suppurative lymphadenitis is caseous lymphadenitis, a disease of sheep and goats caused by *Corynebacterium pseudotuberculosis*. It is also the cause of ulcerative lymphangitis in cattle and horses and pectoral abscesses in horses. In sheep, the bacterium enters the skin through wounds, such as shearing cuts, and then drains to the regional lymph node. This is usually either the superficial cervical (prescapular) or the subiliac (prefemoral) lymph node because the cuts are frequently on the legs. Here a suppurative lymphadenitis develops. Initially there are multiple microabscesses with numerous eosinophils in the sinuses on the cortex. These coalesce and caseate and become encapsulated by fibrous tissue. However, they continue to enlarge, a process that results in the characteristic concentric lamellae, which can often be seen on a cross section of an old abscess. On gross examination, the pus in the abscess is initially greenish (because of the eosinophils) and semifluid (Fig. 13-71), but it becomes caseous with age (Fig. 13-72), loses its green color, and becomes inspissated. Old abscesses can reach a diameter of 4 to 5 cm. Similar abscesses may be found in the lungs, especially in older sheep. The abscesses in goats are usually more numerous and frequently involve lymph nodes of the head and neck.

### 13.2.2.3.2.3.2

#### Granulomatous lymphadenitis

### 13.2.2.3.2.3.2.1

#### Focal granulomatous lymphadenitis.

The classic example of focal granulomatous lymphadenitis is tuberculosis caused by *Mycobacterium bovis*, but the more pathogenic members of the *Mycobacterium avium-intercellulare* complex can cause similar lesions in cattle and pigs. Initially, lesions in the lymphatic system are in the regional lymph nodes (e.g., the tracheobronchial lymph nodes in the case of pulmonary tuberculosis), but once tuberculosis is disseminated, lymph nodes throughout the body will have lesions. *Mycobacterium bovis* lesions in lymph nodes are characterized by the formation of caseating granulomas. These are often multiple (Fig. 13-73) but can become confluent and occupy the whole lymph node. Grossly the lesions are pale, caseous, and often mineralized in cattle. Microscopically the granulomas have central necrotic debris surrounded by

825

a layer of epithelioid macrophages interspersed with scattered Langhans' giant cells and lymphocytes. Peripheral to this is a layer of lymphocytes, and in old lesions the granuloma may be surrounded by a fibrous capsule. Pigs ingesting one of the mycobacteria of the *Mycobacterium avium-intercellulare* complex may have caseous lesions confined to the retropharyngeal lymph nodes, and these lesions are self-limiting. In bovine Johne's disease, the mesenteric lymph nodes draining the infected intestine can have noncaseous granulomas (Fig. 13-74).

**Fig. 13-71 Caseous lymphadenitis, *Corynebacterium pseudotuberculosis*, lymph node, sheep.** The whole lymph node has been replaced by an abscess containing mostly semifluid yellowish pus. This is an early stage of caseous lymphadenitis, before the pus has become inspissated and caseous. (Courtesy Dr. K. Read, College of Veterinary Medicine, Texas A&M University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Fig. 13-72 **Chronic caseous lymphadenitis, *Corynebacterium pseudotuberculosis*, lymph node, sheep.** The lymph node has been sliced longitudinally exposing three chronic abscesses enclosed by thick fibrous capsules and containing yellowish caseous pus. (Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Fig. 13-73 **Tuberculosis (*Mycobacterium bovis*), lymph node, ox.** The normal architecture of the lymph node has been completely obliterated by multiple caseating granulomas, typical of *Mycobacterium bovis* lesions. (Courtesy Dr. M. Domingo, Autonomous University of Barcelona; and Noah's Arkive, College of Veterinary Medicine, University of Georgia.)

Fig. 13-74 **Johne's disease (*Mycobacterium avium* ssp. *pseudotuberculosis*), lymph node, ox.** Several noncaseating granulomas (*pale areas*) have replaced the normal lymphoid tissue (*blue*). Note the Langhans' giant cell (*upper right*). H&E stain. (Courtesy College of Veterinary Medicine, University of Illinois.)

13.2.2.3.2.2.2

### Focal coalescing granulomatous lymphadenitis.

Blastomycosis and cryptococcosis are examples of focal coalescing granulomatous lymphadenitis. Both of these frequently involve a regional lymph node draining an affected area (e.g., the tracheobronchial lymph nodes in the case of pulmonary infections). In advanced cases, the lymph node may be enlarged, the cut surface pale, and its normal architecture totally or almost completely obliterated (Fig. 13-75). In cryptococcosis in cats, there may be little or no inflammatory response (Fig. 13-76), and the enlargement of the lymph node is due mainly to a large mass of organisms (*Cryptococcus neoformans*).

Fig. 13-75 **Cryptococcosis (*Cryptococcus neoformans*), right mandibular lymph node, cat.** The lymph node is grossly enlarged and the incised surface is bulging and pale, and its normal architecture has been completely effaced. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 13-76 **Cryptococcosis, right lymph node, cat.** The pale area in the upper center is occupied by *Cryptococcus neoformans*. In H&E stained sections, the capsule of the organism, which is thick, does not stain. The mass of cryptococci is bordered by the diffuse lymphoid tissue of the paracortex. Note the complete absence of any inflammation (usually granulomatous), which frequently occurs in feline cryptococcosis. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

826

An unusual example of a focal granuloma is the foreign body granuloma that develops around *Demodex* that have drained to a regional lymph node from an area of skin affected with chronic demodicosis.

827

### 13.2.2.3.2.3.2.3

#### Diffuse granulomatous lymphadenitis.

Diffuse granulomatous lymphadenitis is usually caused by dimorphous fungi. Both *Histoplasma capsulatum* and *Blastomyces dermatitidis* can cause this type of diffuse lesion, but in the early stages the lesions will be microscopic foci that later expand and coalesce to involve most of the lymph node.

Histoplasmosis caused by *Histoplasma capsulatum* is a diffuse disease of the monocyte-macrophage system and causes a marked proliferation of macrophages in a wide variety of tissues including spleen, lymph nodes, liver, lungs, and intestine. The dimorphic fungus *Histoplasma capsulatum* grows as a mold in soil and as a yeast in animal tissue. The fungus is distributed throughout the world, in major river valleys, and in temperate and tropical climates; *Histoplasma capsulatum* grows especially well in soil enriched by bird feces. The greatest incidence of disease is in dogs; the incidence is lower in cats.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

In most animals, the organism is inhaled and results in mild self-limiting infections. These are self-limiting but cause enlargement of tracheobronchial lymph nodes. Dogs and cats are usually asymptomatic. Because the fungus is confined to monocytes and macrophages, its spread beyond the respiratory tract is assumed to occur by hematogenous and lymphogenous dissemination of infected cells. Disseminated histoplasmosis in dogs and cats results in gastrointestinal or hepatic disease of long duration.

Disseminated histoplasmosis is characterized by neutrophilia and monocytosis in some animals. Nonregenerative anemia is common because of the chronic inflammation. Nonspecific changes as a result of the damage to the liver are elevated serum alkaline phosphatase activity and hyperbilirubinemia. The total serum protein may be low, normal, or increased, depending upon factors such as extent and duration of the diarrhea and emaciation.

Cytology is useful for the diagnosis of histoplasmosis. The least invasive procedures include examination of cells of body fluids, tracheal wash preparations, and aspirates of bone marrow and lymph nodes. The organisms are visible in macrophages (Fig. 13-77).

Dogs dying of this disease are emaciated. The large bowel is thickened with mucosal corrugations caused by infiltration of the submucosa and lamina propria by macrophages, lymphocytes, and plasma cells. Lymph nodes are uniformly enlarged, and normal architecture may be obscured. In contrast to lymphoma, the nodes are firm when incised.

Histologically in the lymph nodes, coalescing granulomas replace the normal cortical lymphoid tissue. Typical yeast organisms, which are 2- to 4- $\mu$ m-wide hematoxylinophilic dots surrounded by a clear halo, are present in variable numbers in epithelioid macrophages (Fig. 13-78). The spleen and liver are enlarged and firm, and the liver is diffusely gray. Affected organs can be imprinted on glass slides for cytologic evaluation.

**Fig. 13-77 Histoplasmosis, feline transtracheal wash.** A macrophage is laden with small, oval, encapsulated yeast forms. Wright's stain. (Courtesy Dr. M.M. Fry, College of Veterinary Medicine, University of Tennessee.)

**Fig. 13-78 Histoplasmosis, lymph node, dog.** Diffuse granulomatous lymphadenitis. Most of the field is occupied by macrophages, many of which have phagocytosed *Histoplasma capsulatum*. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Leishmaniasis is a disease of the monocyte-macrophage system caused by protozoa of the genus *Leishmania*. It occurs in human beings, dogs, and other animals and is confined to endemic areas, including parts of Europe, the Mediterranean, the Middle East, Africa, and Central and South America. It may be seen in any part of the world in dogs that have resided in endemic areas. The protozoa proliferate by binary fission in the gut of the sand fly and become flagellated organisms, which are introduced into mammals by insect bites; they then assume a nonflagellated form in macrophages.

827

828

Lesions are of two types: cutaneous and/or visceral. The cutaneous lesions in dogs are ulcers at the site of insect bites. These ulcers are directly attributable to proliferation of the organism within macrophages; the accumulation of neutrophils, lymphocytes, and plasma cells; and focal disruption of the dermis and epidermis. In the visceral form of the disease, dogs are emaciated and have general enlargement of abdominal lymph nodes. Dogs have a nonregenerative anemia and a polyclonal hypergammaglobulinemia with total protein concentrations that may exceed 100 g/L (10 g/dL).

At necropsy, dogs with visceral leishmaniasis are emaciated and have an enlarged liver, spleen, and lymph nodes. Histologically the lymph node sinuses are filled with macrophages (sinus histiocytosis), which are filled with intracytoplasmic organisms. Lymph node aspirates contain macrophages, in which there are organisms. Imprints made of these enlarged organs have macrophages containing numerous round organisms approximately 2  $\mu$ m in diameter. They have a vesicular nucleus and a small kinetoplast, which aids in distinguishing them from *Histoplasma*

## Pathologic Basis of Veterinary Disease, 4th Edition

*capsulatum* (Fig. 13-79). The bone marrow is usually hyperplastic. Late in the disease there is usually atrophy of the lymph nodes and spleen.

13.2.2.3.2.3.2.4

### Mixed inflammatory response.

A mixed inflammatory response in the lymph node occurs in reaction to continued drainage from an inflammatory site, such as a joint with chronic erysipelas arthritis (pig) or chronic mastitis (bovine). The lymph node is enlarged because of follicular lymphoid hyperplasia, plasmacytosis (immune response), fibrosis, sinuses histiocytosis, and microabscesses. Also there may be hemosiderosis.

**Fig. 13-79 Leishmaniasis, *Leishmania* spp., canine popliteal lymph node aspirate.** A macrophage contains multiple amastigotes with oval nuclei and smaller bar-shaped kinetoplasts (arrow). Wright's stain. (Courtesy Dr. M.M. Fry, College of Veterinary Medicine, University of Tennessee.)

13.2.2.3.2.4

### Primary neoplasms

The most common primary neoplasm is lymphoma (lymphosarcoma). Many forms of this cause notable enlargement of lymph nodes (Figs. 13-80 and 13-81), and on cross section the normal architecture (cortex and the medulla) may be obliterated by the malignant cells. The cut surface is pale, is often homogeneous, and bulges (see Hematopoietic Neoplasms).

Fig. 13-80 **Lymphoma (lymphosarcoma), cranial mediastinal lymph nodes, cat.** The cranial mediastinal lymph nodes are grossly enlarged, fill the cranial thoracic cavity, and have displaced the lungs and heart caudad. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 13-81 **Lymphoma (lymphosarcoma), bovine lymph node.** Normal architecture of lymph node has been completely obliterated by proliferating lobules of neoplastic tissue composed of malignant lymphocytes. (Courtesy College of Veterinary Medicine, University of Illinois.)

828

## 13.2.2.3.2.5

### Metastatic neoplasms

Carcinomas typically metastasize to the regional lymph node, at least initially. The hematogenous route is typical of metastasis of sarcomas but is often seen with carcinomas. Thus metastatic carcinomas in regional lymph nodes are a common finding, and these lymph nodes may, at least temporarily, prevent further dissemination of the neoplasm. An incomplete list includes squamous cell carcinoma, mammary carcinoma, gastric carcinoma, pulmonary carcinoma, osteogenic sarcoma, malignant melanoma, and malignant mast cell tumor.

If the tumor has induced an inflammatory response at its primary site (e.g., from ulceration such as that caused by an ulcerating squamous cell carcinoma or a perforating gastric carcinoma), this will cause an acute lymphadenitis in the regional lymph node.

Histologically, single cells or clusters of neoplastic cells travel via the afferent lymphatics and are deposited in a sinus, usually the subcapsular sinus. Here the cells proliferate and can ultimately occupy the whole lymph node. They can also send more malignant cells to the next lymph node in the chain.

Lymphoma can be primary or metastatic and both appear grossly similar. The different types of lymphoma are discussed in the section on hematopoietic neoplasia.

## 13.2.2.3.3

### Pigment in Lymph Nodes

Lymph nodes may have the following discolorations:

- **Red**—This may be due to erythrocytes draining from a hemorrhagic or acutely inflamed area, or from hyperemia of the lymph node in acute lymphadenitis. Because of the peculiar anatomy of the porcine lymph node, with large sinuses under the capsule, blood in these nodes is very obvious. It is frequently seen in acute septicemias, in which endotoxin-induced vasculitis or DIC have caused hemorrhages. Histologically, initially there are erythrocytes in the sinuses, and these rapidly undergo erythrophagocytosis by sinus histiocytes, which rapidly increase in number (sinus histiocytosis). If the animal lives, hemosiderin deposits are present within 7 to 10 days in the perisinusoidal macrophages.
- **Black**—Carbon from pulmonary anthracosis drains to the tracheobronchial lymph nodes and from skin tattoos draining to the regional lymph node.
- **Melanin**—In chronic dermatitis, melanocytes may be destroyed and their melanin released into the dermis (so-called pigmentary incontinence), and the pigment is then transported in macrophages to the regional lymph node. Also, lymph nodes draining areas of congenital melanosis, such as in porcine lungs, may have melanin deposits. Malignant melanomas, metastasizing to the regional lymph node, may also be black.
- **Parasitic hematin**—This pigment produced by *Fascioloides magna* in the livers of cattle and *Fasciola hepatica* in the livers of sheep is transported to the hepatic (portal) lymph nodes.
- **Brown**—Hemosiderin imparts a brown coloration to lymph nodes. This can be due to a breakdown of erythrocytes arriving in the afferent lymph from a congested (e.g., chronic passive congestion of the lungs), hemorrhagic or inflamed area or from the phagocytosis of altered or parasitized

## Pathologic Basis of Veterinary Disease, 4th Edition

erythrocytes in hemolytic anemias. Another cause is drainage of iron dextran to the lymph node from an intramuscular injection site.

The lymph nodes of cattle and sheep are often normally discolored by a brown to blackish pigment.

### 13.2.2.3.4 Miscellaneous Lymph Node Disorders

#### 13.2.2.3.4.1 Inclusion bodies

Many viruses produce inclusion bodies, and some of these have inclusions in lymph nodes. These include cytomegalic virus in inclusion body rhinitis of pigs, EHV-1 in horses, parvovirus in feline panleukopenia, and the virus of pseudorabies in pigs.

#### 13.2.2.3.4.2 Emphysema

Emphysema in lymph nodes is a consequence of emphysema in their drainage fields and is seen most frequently in the tracheobronchial lymph nodes in bovine interstitial emphysema and in the porcine mesenteric lymph nodes in intestinal emphysema. The appearance of the lymph node varies with the extent of the emphysema. In severe cases, the lymph node is light, puffy, and filled with discrete gas bubbles, and the cut surface may be spongy. Histologically, the sinuses are distended with gas and their walls are lined by macrophages and giant cells. This change has been considered a foreign body reaction to the gas bubbles. Similar lesions are seen in afferent lymphatics.

### 13.4 APPENDIX 13-1 TESTS TO EVALUATE PLATELET FUNCTION OR IMMUNE-MEDIATED THROMBOCYTOPENIA

- *Bleeding time (template bleeding time, buccal mucosal bleeding time)*. This assay assesses primary hemostasis (platelet plug formation) by measuring the time interval between inflicting of standardized wound and cessation of bleeding. Sedation may be required. In small animals, the test is usually performed on the buccal mucosa; in large animals, it may be performed on the distal limb. Prolonged bleeding time may be because of a platelet function defect, von Willebrand disease, or a vascular defect. The test is of low sensitivity; reference intervals are species- and site-dependent (can perform test on a normal animal as a control). This test is contraindicated in cases of thrombocytopenia because significant thrombocytopenia can cause a prolonged bleeding time (invalidates interpretation of test results).

830

- *Clot retraction test*. This assay assesses retraction of a clot, in which platelets play an essential role. This is a crude test that is rarely performed. Different protocols are described. Significant thrombocytopenia invalidates interpretation of test results.

831

- Tests to characterize platelet function abnormalities more specifically are available through specialized laboratories
  - *Aggregometry*—to assess platelet aggregation in response to different physiologic agonists
  - *Adhesion assays*—to assess the ability of platelets to adhere to a substrate (e.g., collagen)
  - *Flow cytometry*—to assay for expression of surface molecules
  - *PFA-100*—an instrument that simulates a damaged blood vessel, by measuring time for a platelet plug to occlude an aperture; to date, this instrument has mainly been used in research applications
- Tests for immune-mediated thrombocytopenia (IMT)
  - *Flow cytometry*—to detect immunoglobulin bound to the platelet surface, using a fluorescent-labeled antibody

## Pathologic Basis of Veterinary Disease, 4th Edition

---

- *Bone marrow immunofluorescent antibody (IFA) test*—to detect bound immunoglobulin. Sometimes referred to as the “antimegakaryocyte antibody test,” this assay actually detects the presence of immunoglobulin nonspecifically: A smear of a bone marrow aspirate is incubated with a fluorescent-labeled antibody to species-specific immunoglobulin.

### 13.5 TESTS FOR EVALUATING THE COAGULATION SYSTEM

- Activated partial thromboplastin time (aPTT or PTT)
  - Required sample: citrated plasma
  - Measures time for fibrin clot formation after addition of a contact activator, calcium, and a substitute for platelet phospholipid
  - Deficiencies/dysfunction in intrinsic and/or common coagulation pathway (all factors except for VII and XIII) will cause prolongation of PTT.
  - Insensitive test—prolongation requires 70% deficiency
  - Other causes of prolongation include polycythemia (less plasma per unit volume, so excess amount of citrate is available to chelate calcium) and heparin therapy.
- Activated clotting time (ACT)
  - Required sample: nonanticoagulated whole blood in special ACT tube (diatomaceous earth as contact activator)
  - Used in practice setting—performed by warming sample to body temperature, monitoring for clot formation; normal clotting times are within 60 to 90 seconds in dogs, 165 seconds in cats
  - Less sensitive version of PTT—prolongation requires 95% deficiency
  - Severe thrombocytopenia may cause prolongation
- One stage prothrombin time (OSPT or PT)
  - Required sample: citrated plasma
  - Measures time for fibrin clot formation after addition of tissue factor (TF, thromboplastin), calcium, and a substitute for platelet phospholipid
  - Deficiencies/dysfunction in extrinsic (factor VII) and/or common coagulation pathway will cause prolongation of PT
  - Insensitive test—prolongation requires 70% deficiency
- PIVKA (*proteins induced by vitamin K antagonism or absence*) test
  - Required sample: citrated plasma

## Pathologic Basis of Veterinary Disease, 4th Edition

---

- Essentially, a version of the PT using an especially sensitive thromboplastin reagent
  - PIVKA are inactive (uncarboxylated) vitamin K–dependent factors; an increase in PIVKA is not specific for vitamin-K antagonism but may be an earlier and more sensitive detector than PT or PTT.
  - Thrombin time (TT)
    - Required sample: citrated plasma
    - Measures time for fibrin clot formation after thrombin (factor IIa) is added
    - Defects directly involving formation and/or polymerization of fibrin will prolong this test (i.e., if the lesion is upstream of the conversion of fibrinogen to fibrin, the TT will be normal). Hypofibrinogenemia or dysfibrinogenemia will cause prolongation of the TT.
  - Fibrinogen
    - Required sample: citrated plasma
    - Fibrinogen concentration measured based on time to clot formation after addition of thrombin; this is essentially the same as the thrombin time mentioned earlier and is a more accurate method than the heat precipitation method.
    - Decreased fibrinogen may be because of increased consumption (disseminated intravascular coagulation [DIC]) or decreased production (liver disease).
    - Increased fibrinogen is associated with inflammation, renal disease, and dehydration.
  - Fibrin degradation products (FDPs)
    - Required sample: special FDP tube
    - Used in the practice setting
    - Performed by adding blood to a special tube containing thrombin and a trypsin inhibitor (sample clots almost instantly in normal dogs and cats) and incubating two dilutions of serum (1:5 and 1:20) with polystyrene latex particles coated with sheep anti-FDP antibodies (should be negative in normal dogs and cats, but positives have been reported in normal cats)
- 
- D-dimer
    - Required sample: citrated plasma
    - Latex agglutination test
    - To date, only validated in dogs and horses
    - Assay detects a specific type of FDP resulting from *breakdown of cross-linked fibrin*; concentration of plasma D-dimer indicates the degree of fibrinolysis; often used as part of a DIC panel; can be used as a negative predictor to rule out pathologic thrombosis (e.g., pulmonary thromboembolism); will also be increased when there is appropriate clotting.

831

832

## Pathologic Basis of Veterinary Disease, 4th Edition

---

- Antithrombin (a.k.a. antithrombin III, ATIII)
  - Required sample: citrated plasma
  - Decreased because of decreased production (liver disease), loss (protein-losing nephropathy or enteropathy), consumption (DIC), chronic heparin therapy
- Specific factor assays
  - Required sample: citrated plasma
  - Performed at specialized laboratories

## 14 Chapter 14 Nervous System\*

JAMES F. ZACHARY

### 14.1 Central Nervous System

#### 14.1.1 INTRODUCTION

##### 14.1.1.1 ORGANIZATION OF THE CENTRAL NERVOUS SYSTEM

The central nervous system (CNS) consists of neurons, glia, ependyma, endothelial cells and pericytes of blood vessels, and the meninges (Fig. 14-1, Box 14-1). Neurons vary in size, shape, and function, and their cell bodies are organized into functional groups, such as nuclei, gray columns, and cerebral lamina. Neuronal processes called axons and dendrites traverse through the brain and spinal cord, the former often as organized bundles (tracts, fasciculi) forming synapses on cell bodies, dendrites, and axons of other functionally related neurons. It is estimated that there are  $1 \times 10^{11}$  neurons in the human brain. Each neuron makes approximately 10,000 synapses with other neurons; therefore there are about  $1 \times 10^{15}$  synapses in the human brain.

Exactly which cells are classified as glia has varied over the last few decades. Originally, histologists included astrocytes (astroglia), oligodendrocytes (oligodendroglia), ependymal cells (ependymocytes), and microglia as glial cells; however, they currently recognize astrocytes, oligodendrocytes, and microglia as glial cells. Some classification schemes list astrocytes and oligodendrocytes as macroglia. Astrocytes, oligodendrocytes, and ependymal cells are derived from neuroectoderm; whereas microglia, part of the monocyte-macrophage system, are derived from mesoderm (bone marrow). In the mammalian CNS, glia outnumber neurons 10 to 1. Ependymal cells line the ventricular system, whereas choroid plexus epithelial cells form the outer covering of the choroid plexuses.

The CNS is arranged to form two basic parts: the gray and white matter (Figs. 14-2 and 14-3). In the CNS, gray matter is found in the cerebral cortex, in the cerebellar cortex and cerebellar roof nuclei, around the base of the cerebral hemispheres (basal nuclei [often called basal ganglia]: caudate nucleus, lentiform nucleus [putamen, globus pallidus], amygdaloid nucleus, claustrum), and throughout the brain stem often in nuclei. The gray matter is typified by numerous neuronal cell bodies plus a feltwork of intermingled thinly myelinated axons and dendrites, their synaptic junctions, and processes of oligodendroglia, astrocytes, and microglia. This network of processes and synapses in the gray matter is referred to as the neuropil. The white matter consists of well-myelinated axons that arise from neuronal cell bodies in the gray matter and terminate distally in synapses or myoneuronal junctions, plus oligodendroglia, astrocytes, and microglia. In the cerebral hemispheres, white matter is located centrally; whereas in the brain stem, white matter is intermingled with gray matter (nuclei). In the spinal cord, white matter is located peripherally surrounding the gray matter.

The exterior of the CNS is covered by the meninges. The meninges consist of three layers named from outermost to inner most layers as the dura mater, arachnoid, and pia mater. The arachnoid and pia enclose the subarachnoid space.

\* Portions of this chapter are from the third edition and were written by R.W. Storts and D.L. Montgomery.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 14.1.1.2 CELLS OF THE CENTRAL NERVOUS SYSTEM

#### 14.1.1.2.1 NEURONS

The structure and basic cellular biology of neurons is similar to that of other cells (Fig. 14-4); however, there are, as discussed later, some notable differences. The neuron consists of three structural components: dendrites, a cell body, and a single axon. The length of the axon varies depending on the function of the neuron. The length of axons of motor or sensory neurons can be 10,000 to 15,000 times the diameter of the neuronal cell body, which results in these axons being several meters in length. The axon terminates in synaptic processes or neuromuscular junctions.

834

Fig. 14-1 Cell types in the central nervous system include neurons, astrocytes, oligodendroglia, microglia, ependymal cells, choroid plexus epithelial cells, and vascular endothelial cells. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Neuronal cell bodies vary considerably in size and shape, from the large neurons of the lateral vestibular nucleus, Purkinje cell layer of the cerebellum, and the ventral gray matter of the spinal cord to the very small lymphocyte-like granule cells of the cerebellar cortex (Fig. 14-5). Neuronal nuclei tend to be vesicular to spherical in shape, tend to be usually centrally located, and often, particularly in large neurons, tend to contain a prominent central nucleolus. Neurons contain focal arrays of rough endoplasmic reticulum and polysomes termed Nissl substance that are responsible for the synthesis of proteins involved in many of the neuron's vital cellular processes such as axonal transport. Nissl substance is present in all neurons, regardless of the size of the cell body, but tends to be more prominent in those cells with voluminous cytoplasm such as motor neurons.

14.1.1.2.1.2	<b>Axonal Transport</b>

In most cells of the body, proteins and other molecules are distributed throughout the cell by simple diffusion. In neurons, simple diffusion alone is inefficient because synapses are a considerable distance away from the cell body of the neuron and molecules cannot diffuse the length of the axon. In addition, there are no systems in axons or synapses to catabolize molecules resulting from normal metabolic processes. Thus these molecules need to be returned to the cell body for processing.

As a result of these structural differences between neurons and other cells, neurons have developed axonal transport systems to efficiently move molecules and cellular organelles from the cell body through the axon to the synapses and their degradation products back to the cell body (Fig. 14-6). Axons can be longer than a meter in length, especially in an animal such as a giraffe. Lower motor neurons, whose cell bodies lie in the ventral gray horn of the spinal cord, and lumbar dorsal root ganglia, whose axons extend to the distal limb and to the caudal medulla, have the longest axons in the body. The neuron expends considerable energy and materials to move biologic materials up and down the axon. Alterations in the function of these transport systems can lead to neuronal dysfunction.

These transport systems are divided into “fast axonal transport” and “slow axonal transport.” The fast axonal transport system has an anterograde component (toward the synapse) and a retrograde component (toward the cell body). The slow axonal transport system has only an anterograde component (toward the synapse).

Fast anterograde axonal transport (up to 400 mm per day) moves materials not intended for use in the cytoplasm of the neuron cell body. These materials formed from the Golgi apparatus are principally membrane-bound vesicles. They include mitochondria and membranous vesicles that contain peptide neurotransmitters, small transmitter molecules, and the enzymes necessary for their activation. These materials are moved down the axon on microtubules by specialized protein motors composed of kinesin and kinesin-related proteins using adenosine triphosphate (ATP) as an energy source.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Fast retrograde axonal transport (200 to 300 mm per day) returns endosomes, mitochondria, and catabolized proteins to the cell body of the neuron for degradation in lysosomes and reuse. This transported material is returned on microtubules, by dynein and microtubule-associated adenosine triphosphatase (ATPase) in the axon. This system will also transport certain toxins, such as tetanus toxin, and viruses, such as rabies virus, from the periphery via the peripheral nervous system (PNS) into the CNS.

Slow anterograde axonal transport (0.2 to 5 mm per day) transfers throughout the axon via	835
microtubules, the major cytoskeletal proteins, such as microtubule and neurofilament proteins, that are	836
necessary to maintain the structural integrity and transport systems within the axon.	

---

Fig. 14-2 **Organization of the brain, gray matter, and white matter.**

**A**, Transverse section at the level of the thalamus, dog. Gray matter (*darker areas*) of the cerebral cortex lie beneath the leptomeninges on the external surface of the brain, whereas in the thalamus there tends to be a mixture of gray and white matter. Major white matter areas (*light areas*) include corona radiata, centrum semiovale, and corpus callosum of the cerebrum, and internal capsule and optic tracts bordering the lateral and ventral surfaces of the thalamus, respectively. **B**, Gray matter consist primarily of the cell bodies of neurons (*arrows*) and a network of intermingled thinly myelinated axons, dendrites, and glial cell processes. This network is referred to as the neuropil (*N*). Other components include oligodendroglia (perineuronal satellite cells) (*arrowheads*), protoplasmic astrocytes, and microglia. H&E stain. **C**, White matter primarily consists of well-myelinated axons (*arrows*) plus oligodendroglia (*arrowheads*) and fibrous astrocytes. The clear spaces surrounding large axons are artifacts formed when the lipid components of myelin lamellae are dissolved away by solvents in the preparation of paraffin embedded sections. H&E stain. (**A**, **B**, and **C**, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Diseases of the axon that result directly or indirectly from alterations in axonal transport systems are discussed later. The character of the histologic lesions affecting injured nerve fibers can often be related to alterations in specific transport systems. Neurofilament proteins are synthesized in the neuronal cell body and are assembled and transported into axons. If neurofilaments accumulate in neuronal cell bodies and proximal axons, this lesion is called an axonopathy and is characterized by alterations in slow transport systems, which results in axonal swelling or atrophy and perikaryal neurofibrillary accumulations. Axonal injury and alterations in neurofilament transport can also cause secondary demyelination.

836

**Fig. 14-3 Organization of the spinal cord, gray matter, and white matter.** **A**, White matter in the spinal cord is located peripherally and divided into dorsal, lateral and ventral funiculi. As a general rule, dorsal funiculi (*D*) consist of ascending sensory axons, lateral funiculi (*L*) have a mixture of sensory and motor axons, and ventral funiculi consist of descending motor axons (*V*). *DGH*, Dorsal gray horn; *VGH*, ventral gray horn. Histologically, the right side is a mirror image of the left side. **B**, Transverse section of spinal cord, ventral gray horn, horse. The cell bodies of large motor neurons (*arrows*) are those of lower motor neurons and their axons extend in peripheral nerves to myoneural junctions that innervate skeletal muscle. **C**, Transverse section of spinal cord, ventral funiculus, horse. Because most axons course up and down the length of the spinal cord, in a transverse section, axons (*arrows*) are cut in cross section. They are surrounded by myelin sheaths whose lipid components are dissolved out during the preparation of paraffin embedded sections, resulting in clear spaces that are an artifact. H&E stain. (*A*, *B*, and *C*, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

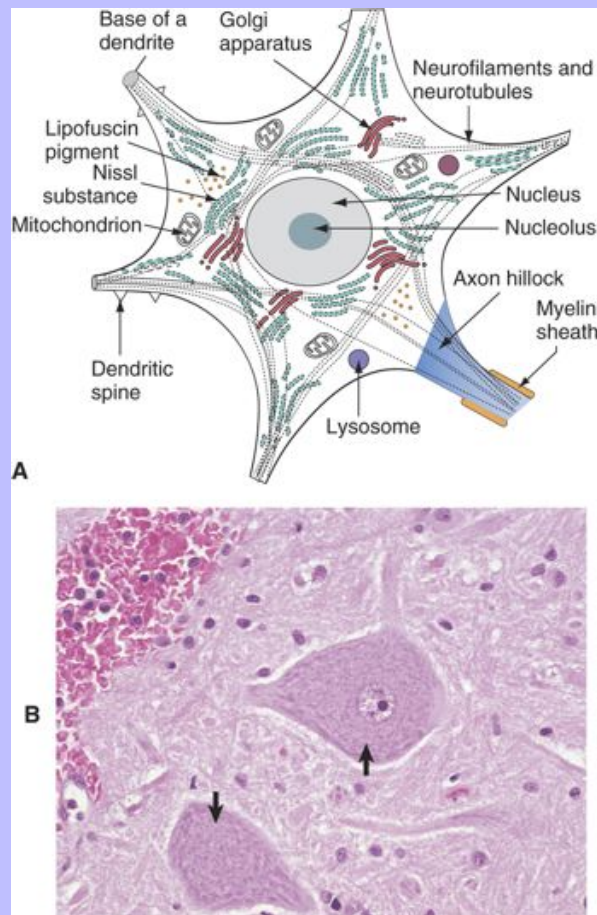

Fig. 14-4 **Neuron structure.** **A**, Basic cell biology and structure of neurons are similar to other cells in the body. Additionally, neurons have dendritic arborizations and an axon, specializations for the initiation, propagation, and transmission of impulses that underlie the basic function of these cells. **B**, The cytoplasm of the neuronal cell body has blue (basophilic [H&E stain]) granular material (rough endoplasmic reticulum) called Nissl substance (*arrows*). Nissl substance synthesizes proteins, including precursor neurotransmitter proteins and the structural proteins, (neurofilaments) active in maintaining the integrity (length and diameter) of the axon. H&E stain. (**A**, Modified from Kierszenbaum AL: Histology and cell biology, St Louis, 2002, Mosby. **B**, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

14.1.1.2.1.3

### Membrane Potentials and Transmitter/Receptor Systems

A fundamental activity of neurons is to modulate and effectively transmit chemical and electric signals from one neuron to another via synapses in the CNS or from one neuron to a muscle cell via junctional complexes, myoneural junctions, or motor end plates in the PNS. The process of nerve impulse conduction is made possible by the establishment and maintenance of an electric potential across the cell membrane of the neuron/axon. Membrane potential is the difference in voltage between the inside and outside of the neuronal/axonal cell membrane and is called the resting potential. This potential is established and maintained by a membrane sodium-potassium ATPase pump. The pump keeps the concentration of sodium ions outside the cell approximately 10 times greater than inside the cell, and the concentration of potassium ions inside the cell 20 times greater than outside the cell. The differences in concentrations of sodium ions outside and potassium ions inside of the cell membrane keep the membrane resting potential at approximately  $-70$  mV. Thus the inside of the neuron/axon is 70 mV less than the outside. Sodium and potassium ions will leak across the cell membrane, and therefore concentration gradients are maintained by the sodium-potassium ATPase pump in the cell membrane. This established equilibrium and the membrane potential places the neuron in a “resting” condition, ready to generate an action potential.

837

838

**Fig. 14-5 Variations in neuronal morphology, cerebellum, granule cells, and Purkinje neurons, normal animal.** The granule cell neurons of the cerebellar cortex (*arrowheads*) are very small lymphocyte-like cells that have relatively little demonstrable Nissl substance when compared with Purkinje neurons (*arrows*) and large motor neurons (depicted in [Fig. 14-3, B](#)). H&E stain. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

**Fig. 14-6 Axonal transport systems.** Neurotransmitter vesicles and neurofilament proteins, synthesized in the rough endoplasmic reticulum and packaged in the Golgi apparatus are transported through the length of the axon and to synapses by kinesin. Kinesin is a microtubule motor protein that uses chemical energy from adenosine triphosphate hydrolysis to generate mechanical force and thus bind to and move attached to microtubules. Used vesicles and effete neurofilament proteins are returned along a microtubule (recycled) to the neuron cell body by cytoplasmic dynein, another microtubule motor protein. These transport systems are used by some pathogens (rabies virus, *Listeria monocytogenes*) to enter and spread within the central nervous system. (Modified from Kierszenbaum AL: Histology and cell biology, St Louis, 2002, Mosby.)

An action potential arises when a neuron transmits information down an axon, away from the neuronal cell body. An action potential is initiated by an event that depolarizes the cell membrane and causes the resting potential to move toward 0 mV. When depolarization reaches a threshold level of approximately -50 mV, an action potential will occur. Once initiated, the strength of an action potential is always the same because the action potential is an intrinsic property of the neuron cell body and its axon.

838

839

**Fig. 14-7 Resting and action potentials.** Nerve impulse conduction is made possible by the establishment and maintenance of an electric potential across the cell membrane of the neuron/axon. Resting membrane potential is established and maintained by differences in concentrations of potassium ions inside and sodium outside of the cell membrane. Sodium and potassium ions will leak across the cell membrane, and therefore concentration gradients are maintained by a sodium-potassium pump in the cell membrane. When an event depolarizes the cell membrane to a threshold level of approximately  $-50$  mV, an action potential will occur. **A**, An action potential is initiated by an event that opens sodium channels, and the action potential is propagated along the cell membrane by the sequential opening of voltage-gated sodium channels in adjacent sections of the membrane. AP, Action potential. **B**, The action potential is regenerated in adjacent sections of the cell membrane as additional sodium channels open. Depolarized segments repolarize as sodium channels close and potassium ions move out of the cell. AP, Action potential. (*A and B, From Copstead LC, Banasik JL: Pathophysiology: biological and behavioral perspectives, ed 2, Philadelphia, 2000, Saunders.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Action potentials are caused by the movement of sodium and potassium ions across the neuron cell body/axon cell membrane. With an initiating event, sodium channels are first to open, and large concentrations of sodium ions enter the intracellular microenvironment (Fig. 14-7). Because sodium ions are positively charged, the polarity becomes more positive ( $-70$  mV to  $-50$  mV) and the neuron/axon becomes depolarized. Potassium channels open later in the depolarization process, concurrently with the closing of sodium channels. Potassium ions leave the cell and enter the extracellular fluid. These events cause repolarization of the neuron/axon and a return to a resting potential ( $-70$  mV) via the membrane sodium-potassium ATPase pump. Alterations in these ion channels have been correlated with epilepsy in human beings and will likely be discovered in animals.

Action potentials are most commonly initiated by neurotransmitters such as acetylcholine acting through synapses, but they also occur as a result of mechanical stimuli, such as stretching and sound waves. There are two main classes of synapses: inhibitory and excitatory. Stimulation of inhibitory synapses results in inhibitory postsynaptic potentials that cause hyperpolarization of dendrites and cell bodies. Hyperpolarization decreases the membrane potential (more negative,  $-80$  mV), thus making the neuron less likely to reach the threshold for an action potential. Inhibitory neurotransmitters include  $\gamma$ -aminobutyric acid (GABA), glycine, dopamine, serotonin, norepinephrine (in the CNS), and acetylcholine (in heart muscle).

Stimulation of excitatory synapses results in excitatory postsynaptic potentials that cause depolarization of the dendrites and cell bodies. Depolarization increases the membrane potential (more positive,  $-50$  mV), thus making the neuron more likely to reach the threshold for an action potential. Excitatory neurotransmitters include glutamate, norepinephrine in the PNS, and acetylcholine in skeletal muscle.

The generation of an action potential is a complicated process requiring depolarization of the cell membrane ( $-50$  mV). Inhibitory and excitatory synapses and their inhibitory and excitatory postsynaptic potentials, respectively, are “summed” through processes termed spatial and temporal summation occurring in the dendritic network of the neuron. Spatial summation reflects additive input from different parts of the dendritic network, whereas temporal summation reflects additive input from stimuli that occur closely in time. This summation process is a graded potential and ultimately determines if the threshold for an action potential will occur.

The action potential is a flow of depolarization that travels down the axon to synapses at the distal axon. When the axon lacks myelin, the flow of depolarization down the axon is called continuous conduction. When the axon is myelinated, the speed of conduction is determined by the degree of myelination of the axon and is called saltatory conduction. The diameter of unmyelinated axons can range from  $0.2$  to  $1\text{ }\mu\text{m}$  with action potential velocities ranging from  $0.2$  to  $2$  m/sec, whereas the diameter of myelinated axons can range from  $2$  to  $20\text{ }\mu\text{m}$  with action potential velocities ranging from  $12$  to  $120$  m/sec. The greater the degree of myelination, the faster the speed of impulse conduction down the axon. In unmyelinated axons, action potentials are conducted at a relatively “slower” velocity by the process of ion exchange (continuous conduction). In myelinated axons, action potentials are conducted at a relatively “faster” velocity by a mechanism called saltatory conduction. In this process, action potentials move down the myelinated axon using cable properties, like electric current flow in insulated copper wires. This method is fast, efficient, and requires less energy than ion exchange. However, the action potential would decay if axons were myelinated continuously along their length and likely would not reach synapses at full strength or at all. This decay is caused by loss of current across the cell membrane and capacitance properties of the cell membrane as the action potential travels down the axon. To minimize the decay of action potentials, axons are myelinated in segments

839

841

## Pathologic Basis of Veterinary Disease, 4th Edition

---

called internodes. A gap, called the node of Ranvier, is formed between consecutive internodes and measures between 0.2 and 2 mm in length. At this gap, the action potential is restored to full strength by ion exchange. The node of Ranvier is highly enriched in sodium channels, and these channels are essential for impulse propagation via rapid action potential current restoration. Disease processes that disrupt myelination of axons will interfere with saltatory conduction, slow the action potential, and result in clinical dysfunction of the nervous system ([Fig. 14-8](#)).

**Fig. 14-8 Axonal action potential conduction and the effect of demyelination.** The speed of the conduction process is determined by the diameter of the axon and the degree of myelination. As axons increase in diameter, the resistance to ion flow decreases, allowing the action potential to flow faster. In addition, the degree of myelination is directly proportional to the diameter of the axon. Thus the concept that the more myelin the faster the speed of the impulse is true up to the point in which the myelin is normal in thickness. For an axon whose myelin is reduced, conduction of the action potential is slower. Under normal conditions, locomotion is a well-coordinated event that requires precise timing (speed) of impulse conduction to get coordinated movements. If the speed of the action potential is altered by disease, especially demyelination, then the conduction of the action potential will be delayed and what are normally coordinated movements become uncoordinated. **A**, In unmyelinated axons, action potentials are conducted at a relatively “slower” velocity by the process of ion exchange continuous conduction ([Fig. 14-7](#)). **B**, In myelinated axons, action potentials are conducted at a relatively “faster” velocity by a mechanism called saltatory conduction. Optimal function of saltatory conduction is dependent on having the proper degree of myelination of the axon (as determined by axonal diameter) throughout the full length of the axon. **C**, In axons that have lost some but not all of their myelin lamellae from one or more internodes so that there is a “thinner” covering of myelin, the speed of saltatory conduction is reduced because of leakage of the action potential across this thinner myelin sheath, resulting in clinical dysfunction of the nervous system. **D**, In axons that have lost all of their myelin from one or more internodes (complete primary demyelination of the internode), the speed of saltatory conduction is reduced because of the conversion from saltatory conduction to ion exchange continuous conduction in the areas where internodes have lost their myelin. Thus the speed and timing of the action potential is substantially reduced, leading to clinical dysfunction of the nervous system. (*A through D, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.*)

The axon can be a very long extension of the neuron cell body extending, for example, up to 2 m from the lumbar dorsal root ganglion in a giraffe. At its distal end, the axon splits into several branches that end as specialized structures called axon terminals/terminal buttons/synaptic bulbs. Synapses present at these axon terminals are functional, and structural points of contact between “networked” neurons and these synapses convert the action potential into chemical signals that stimulate the next neuron in the conduction pathway. The cell membrane that releases chemical neurotransmitters is called the presynaptic membrane, and the cell membrane that has neurotransmitter receptors for the chemical neurotransmitters is called the postsynaptic membrane. These membranes are found on dendrites and cell bodies of the next neuron in the neural conduction pathway. The gap between the presynaptic and postsynaptic membranes that chemical neurotransmitters must cross is called the synaptic cleft. The mechanism of diseases, such as tetanus and botulism, is manifested through presynaptic and postsynaptic membrane receptors.

When an action potential reaches the axon terminal, it causes the release of chemical neurotransmitters from the presynaptic membrane by opening voltage-gated calcium channels, leading to membrane depolarization. The amount of chemical neurotransmitter released into the synaptic cleft is determined by the number of action potentials that reach the axon terminal over time. Chemical neurotransmitters traverse the synaptic cleft and bind to neurotransmitter receptors on dendrites and cell bodies of a new neuron in the neural conduction pathway.

There are two types of chemical neurotransmitter receptors, ionotropic and metabotropic, on the membrane of postsynaptic neurons. Functionally, these receptor types differ in latency and duration of action. Ionotropic receptors have a fast response and short duration of effect, whereas metabotropic receptors have a slower response and a longer duration of effect. In addition, ionotropic receptors are localized to specific sites on the postsynaptic membrane, whereas metabotropic receptors are distributed diffusely and at random.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Chemical neurotransmitter stimulation of ionotropic receptors results in the opening of ion gates or channels, resulting in depolarization of the postsynaptic membrane. Excitatory neurotransmitters, such as glutamate, open postsynaptic membrane sodium channels. Inhibitory neurotransmitters, such as GABA, open postsynaptic membrane chloride channels.

Chemical neurotransmitter stimulation of metabotropic receptors results in the generation of a second messenger such as in the cyclic adenosine monophosphate (cAMP) pathway, which initiates a sequence of metabolic changes in the neuron. Metabotropic receptors are composed of protein subunits that span the postsynaptic cell membrane. An extracellular component of this protein has a high affinity for neurotransmitters and functions as a binding site. Following binding of the neurotransmitter, the receptor undergoes a configurational change that directly or indirectly activates a cell membrane enzyme, such as intracellular G proteins, leading to the formation of the second messenger. cAMP can activate protein kinase A–induced phosphorylation, leading to functional changes in ion channels and protein transcription. Dopamine is an example of a chemical neurotransmitter that uses metabotropic receptor pathways.

14.1.1.2.2

### ASTROCYTES

The functions of astrocytes in the CNS are regulation, repair, and support, as depicted in [Fig. 14-9](#). Mature astrocytes differentiate from pluripotential progenitor cells during the development of the CNS.

841

Astrocytes are the most numerous cell type in the CNS and have traditionally been classified into two types based on morphology. Protoplasmic astrocytes are located primarily in gray matter, whereas fibrous astrocytes occur chiefly in white matter. Microscopically, astrocytes have relatively large vesicular nuclei, indistinct or inapparent nucleoli, and no discernible cytoplasm with routine hematoxylin and eosin (H&E) staining ([Fig. 14-10](#)). With suitable histochemical stains, metallic impregnation, or immunohistochemical staining for glial fibrillary acidic protein (GFAP [the major intermediate filament in astrocytes]), the cell body and the extensive arborization and interconnections of astrocytic processes can be demonstrated. Processes vary from short and brushlike to long branching processes in protoplasmic and fibrous astrocytes, respectively ([Fig. 14-11](#)). These morphologic features and their corresponding histochemical and immunohistochemical staining reactions serve as important criteria for the classification of tumors of astrocyte origin.

842

**Fig. 14-9 Functions of astrocytes.** Astrocytes provide structural integrity and regulatory oversight, as depicted in this diagram. They: 1, monitor and regulate fluid and electrolyte balances within neurons and surrounding extracellular space; 2, form the glial limitans at the base of the pia mater; 3, interconnect with other astrocytes to provide a system to monitor and regulate fluid and electrolyte balances throughout the central nervous system (CNS); 4, possibly participate in the formation and functions of the blood-brain barrier; 5, participate in the support of axon tracts of functionally related neurons; 6, monitor for and remove excessive release of neurotransmitters in synapses; 7, protect and insulate nodes of Ranvier; and 8, participate in the cerebrospinal fluid–brain barrier. In addition, astrocytes are a reparative (healing) cell following CNS injury with loss of tissue because nervous tissue, per se, is devoid of fibroblasts. Fibroblasts exist in the pia mater and other meninges. Everywhere else, healing is dependent on the astrocyte, which will respond by increased length, branching, and complexity of cellular processes (astrogliosis). The astrocyte has many functions in the nervous system; one of them is to act in healing to produce a scar in attempts to isolate cavities and abscesses. Fibroblasts may also contribute to the formation of a scar, if this cell type is present, as it is in the leptomeninges.

### Functions of Astrocytes

14.1.1.2.2.1.1

#### Regulation of the microenvironment

The microenvironment of the CNS must be under strict control to maintain normal function. Astrocytes are involved in homeostasis of the CNS and regulate ionic and water balance, antioxidant concentrations, uptake and metabolism of neurotransmitters, and metabolism or sequestration of potential neurotoxins, including ammonia, heavy metals, and excitatory amino acid

842

neurotransmitters such as glutamate and aspartate. Interactions between astrocytes, microglia, and neurons orchestrate immune reactions in the brain. In this regard, astrocytes can express major histocompatibility complex (MHC) class I and II antigens, a variety of cytokines and chemokines, and adhesion molecules that modulate inflammatory events in the CNS. Astrocytes also secrete growth factors and extracellular matrix molecules that play a role not only in development but also in repair of the CNS.

843

**Fig. 14-10 Histologic features of glial cells, ventral gray horn, spinal cord, horse.** A neuronal cell body and its processes are in the center of the illustration. To the inexperienced, identifying specific types of glial cells in H&E stained histologic sections can be challenging. Astrocytes (*arrows*) have larger vesicular nuclei (dispersed chromatin) and the cell membrane and cytoplasm are rarely seen in nondiseased conditions. Thus these nuclei just seem to “sit” in the midst of the neuropil. The majority of nuclei in the neuropil here are astrocytic. Oligodendroglial cells (*arrowheads*) have smaller and dense round nuclei (condensed chromatin) often surrounded by a clear zone indicative of cell cytoplasm and a cell membrane. Oligodendroglial cells in gray matter are called perineuronal satellite cells; those in white matter are called interfascicular oligodendrocytes. Microglial cells are difficult to identify in H&E stained sections of the central nervous system, but they often appear as “rod cells,” which have small, dense elongated nuclei (*dashed arrow*). The light pink homogenous tissue distributed in large quantities between these cell types is the neuropil. V, Blood vessels. H&E stain. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

14.1.1.2.2.1.2

### Repair of injured nervous tissue

In the CNS, reparative processes that occur after injury, such as inflammation and necrosis, are chiefly the responsibility of astrocytes. In these reparative processes, astrocytes are analogous to fibroblasts in the rest of the body. Astrocytes do not synthesize collagen fibers, as do fibroblasts. Instead, repair is accomplished by astrocytic swelling and division, and abundant proliferation of astrocytic cell processes containing intermediate filaments composed of GFAP, a process called astrogliosis. As an example, neuronal necrosis occurs in some viral diseases of the CNS. When neurons die, the spaces left by the loss of the neuronal cell bodies are filled and such spaces (<1 mm in diameter) are filled by processes of astrocytes. Larger spaces that form following injury, such as an infarct, are often too large to be filled and therefore exist in the CNS as fluid-filled spaces (cysts) surrounded by a capsule of astrocytic processes. Astrocytes will also attempt to wall off abscesses, but they are not as effective as fibroblasts and the capsule can be incomplete or weak (Fig. 14-12). In the case of direct extension of bacteria from the meninges or meningeal blood vessels, which contain or are surrounded by fibroblasts, respectively, fibroblasts will play a larger role in isolating the inflammatory process.

**Fig. 14-11 Astrocytic processes, brain, cerebral cortex, normal animal.** Processes of astrocytes arborize extensively throughout the central nervous system (structures stained purple). Note that some of the processes are on the outside of blood capillaries (end feet) (arrows). A, Cell body of astrocyte. Holzer's stain. ## Pathologic Basis of Veterinary Disease, 4th Edition

14.1.1.2.2.1.3

### Structural support of the central nervous system

Structurally, astrocytic processes provide support for other cellular elements and ensheath and insulate synapses. Astrocytes also provide guidance and support of neuronal migration during development; thus, tracts and fasciculi of axons with similar functions are arranged and structurally supported by astrocytic processes. Processes of astrocytes (foot processes) also terminate on blood vessels throughout the CNS, forming a component of the blood-brain barrier. Astrocytes influence the induction of tight junctions between endothelial cells that serve as the structural basis for the blood-brain barrier. A dense meshwork of astrocytic processes also forms the glia limitans beneath the pia mater and is variably prominent in subependymal areas. During CNS development, cells termed radial glia provide a scaffold and guidance for migrating neurons. When development is completed, radial glia mature into astrocytes.

843

844

#### Fig. 14-12 **Astrocytic repair, bacterial abscess, brain stem, sheep.**

The abscess has a central core of necrotic debris (*D*) surrounded by a layer of inflammatory cells (*I*) and a less dense pink-staining zone representing an attempt by astrocytes and fibroblasts to form a capsule (*A*). This capsule is formed by fibrous tissue on the ventral and right sides, those sides closest to the pia, which contains fibroblasts. A fibrous capsule is absent from the dorsal and left sides of the abscess, adjacent to brain parenchyma. Here, there is no population of resident fibroblasts and the capsule is formed by astrocytes and their processes, which are often delicate and do not form an effective capsule (*A*). H&E stain.

(Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

### OLIGODENDROGLIA

There are two types of oligodendroglia: (1) interfascicular oligodendrocytes and (2) satellite oligodendrocytes (satellite cells). The function of interfascicular oligodendroglia is myelination of axons, whereas the function of satellite oligodendroglia is thought to be regulation of the perineuronal microenvironment. Oligodendroglia have been compared with neurons with regard to their total cell size in that their processes occupy much more space than the cell body. Neurons have very long axons, which account for their size; oligodendroglia have extensive myelin sheaths, which account for their size. In H&E stained sections, oligodendroglia are often confused with lymphocytes because of the similarity of the morphology of their nuclei and cytoplasmic volume. Interfascicular oligodendroglia and perineuronal satellite oligodendroglia are located primarily in white and gray matter of the CNS, respectively (Fig. 14-13); however, interfascicular oligodendroglia can also be found along axons that traverse through the gray matter. The mature, small oligodendrocyte has a spherical, hyperchromatic nucleus (Figs. 14-10 and 14-13). As with astrocytes, the cell body and processes of this cell do not stain with conventional H&E staining methods and can only be demonstrated following special procedures that include metallic (silver) impregnation and immunohistochemical methods.

844

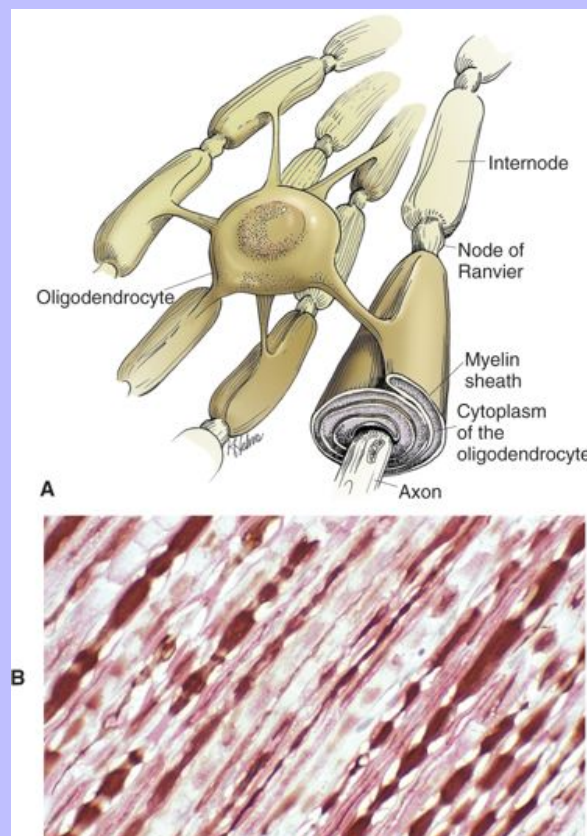

845

**Fig. 14-13 Responses of glial cells to injury in H&E stained central nervous system (CNS) sections.** **A**, White matter. In nondiseased states, oligodendroglia in white matter are often arranged linearly (fascicular oligodendroglia) (*arrow*) and are responsible for the formation of myelin around axons. In gray matter (not shown; see [Fig. 14-10](#)), oligodendroglia are dispersed as individual cells around neuronal cell bodies as perineuronal satellite cells ([Fig. 14-13, B](#)). H&E stain. **B**, Gray matter. When neurons are injured or there exists some perturbation of the perineuronal microenvironment, a long-held belief was that oligodendroglia around neurons hypertrophy and proliferate in a process referred to as satellitosis. Currently, there is no uniform agreement that these cells respond to neuronal injury in this manner. Perineuronal satellite oligodendroglia (*arrows*) surround a small degenerate neuron with condensed chromatin and little cytoplasm. H&E stain. **C**, White matter. Astrocytes (*arrows*) and oligodendroglia (*arrowheads*) have a limited repertoire of responses to injury in the CNS. Astrocytic proliferation can occur but is very difficult to determine in sections stained with H&E. Here, astrocyte nuclei are somewhat enlarged and appear more numerous than expected. H&E stain. **D**, Gray matter. Astrocytes respond to injury in hyperammonemia, such as occurs with hepatic encephalopathy, by forming astrocytes with enlarged, markedly vesicular (“watery”), often elongated nuclei called Alzheimer's type II astrocytes (*arrows*). This type of astrocyte may occur in pairs that are surrounded by a clear space indicative of cellular swelling. H&E stain. (**A**, and **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **C**, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois. **D**, Courtesy Dr. D. Gould, College of Veterinary Medicine, Colorado State University.)

**Fig. 14-14 Central nervous system (CNS) myelin.** Oligodendroglia myelinate axons within the CNS (also see Fig. 14-1). **A**, As depicted in this illustration, each oligodendrocyte sends out numerous cytoplasmic processes that repetitively encircle (myelinate) the portion of an axon between two nodes of Ranvier (internode) on the same and several different axons. Direct or indirect injury to an oligodendrocyte can result in “demyelination” of those internodes myelinated by that oligodendrocyte. This injury will slow the rate of conduction of an action potential, and depending on the site of the lesion may lead to clinical signs of neural dysfunction (ataxia, proprioception deficits). **B**, CNS nerves, longitudinal section. Axons and their neurofilaments (brown stain) and myelin (red stain) are well demonstrated by this immunohistochemical stain for neurofilaments and myelin basic protein. (*A and B*, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Most interfascicular oligodendroglia (Fig. 14-13) are aligned in rows parallel to myelinated axons and are responsible for the formation and maintenance of segments (internodes) of myelin sheaths. One oligodendroglial cell can form as many as 50 different internodes of myelin, each of which can be located on many different axons (Fig. 14-14). Altered function of oligodendroglial cells, as occurs in infectious canine distemper virus (CDV) infection, can cause primary demyelination of these segments resulting in severe neurologic dysfunction. Oligodendroglia also influence maturation and maintenance of axons, and inhibit regeneration of established myelinated axons.

Perineuronal satellite oligodendroglia (Fig. 14-13) are adjacent to neuronal cell bodies and are also located around blood vessels in the gray matter. They are thought by some investigators to regulate the perineuronal microenvironment and respond to perturbation by proliferation. When the perineuronal microenvironment is altered or neuron cell bodies are injured, perineuronal satellite oligodendroglia in an attempt to regulate the environmental perturbation hypertrophy and proliferate in a process referred to as satellitosis. Similarly, alterations in the microenvironment of gray and white matter away from areas surrounding neuron cell bodies results in hypertrophy of oligodendroglia (Fig. 14-13). Finally, satellitosis can be quite prominent in normal CNS in various areas of the gray matter.

### 14.1.1.2.4

#### MICROGLIA

The basic functions of microglia are immunosurveillance, immunoregulation, and reparative (phagocytic) activities following neural cell injury and death. The origin of microglia in the CNS has been debated for years. The current consensus is that the cells originate from circulating monocytes (mesoderm-derived) that enter and populate the CNS during embryonic development and early postnatal life, analogous to the formation of the monocyte-macrophage system in other organs. After entry into the CNS, the cells become amoeboid microglia, phagocytosing dead cells and cellular debris during remodeling and maturation of the CNS. Amoeboid cells then enter a quiescent stage and transform into ramified microglia. Ramified microglia constitute up to 20% of the glial cells and are present throughout the mature CNS, serving as sentinels of brain injury. Ramified microglia, also called resting cells, are most numerous in perineuronal and perivascular areas and in interfascicular locations in white matter. Evidence of pinocytosis in ramified cells suggests some role in maintaining the neural microenvironment. The principal function of microglia is phagocytosis, the initiation of and participation in the innate and adaptive immune responses, and in degenerative and inflammatory diseases of the CNS.

845

846

Microscopically, ramified microglia have small, hyperchromatic ovoid-, rod-, or comma-shaped nuclei and no appreciable cytoplasm with routine H&E staining, hence the term “rod cell” sometimes used to describe them (Fig. 14-10). With special labeling techniques or metallic impregnation, ramified cells have a few delicate branching processes. The small hyperchromatic nuclei and nuclear shape distinguish microglia from astrocytes and oligodendroglia. However, microglia are often difficult to identify in H&E stained sections without some expertise in neuropathology.

Activated microglial cells are not the major source of active macrophages in inflammation of the CNS. Blood monocytes recruited from the circulation account for up to 70% of the macrophages in inflammatory and degenerative diseases of the CNS. These macrophages differentiate from blood monocytes involved in normal “leukocytic trafficking” through the CNS and can be involved in immunologic and phagocytic responses (gitter cells) to disease processes and infectious organisms. They are found mainly in the leptomeninges, choroid plexus, and perivascular areas.

### EPENDYMA (INCLUDING CHOROID PLEXUS EPITHELIAL CELLS)

The basic functions of ependymal cells, which line the ventricular system, are to move cerebrospinal fluid (CSF) through the ventricular system via movement of their cilia and to regulate the flow of materials between the CNS and the CSF. The ependyma is a single-layered, cuboidal to columnar, epithelium that lines the ventricles and mesencephalic aqueduct of the brain, and central canal of the spinal cord (Fig. 14-15). This layer of cells is therefore situated between the CSF and nervous tissue. Ependymal cells have cilia that project into the CSF and beat in a coordinated manner in the direction of CSF flow. Other structures, referred to as circumventricular organs, which include the choroid plexuses, are covered by highly specialized ependymal cells. The surface of ependymal cells that form the choroid plexus have microvilli (microvillus border) and cilia that occur singly or more often in groups of three or more. The choroid plexus epithelial cells also have specialized tight junctions (zonulae occludentes) that are a functional part of the blood-CSF barrier. In contrast to the choroid plexus, junctions between the conventional ependymal cells include gap junctions (transmembrane proteins form a pore allowing communication between adjacent cells), and zonulae and fasciae adherentes, which permit movement of materials such as proteins from the CSF into the extracellular space of the brain. This cellular lining, however, is not a static membrane in that it regulates several processes that involve interaction between the CSF and brain. The functions include regulation of fluid homeostasis between the ventricular cavities and the brain, secretion and absorption of CSF, endocytosis, phagocytosis, and metabolism of substances such as iron resulting from the lysis of erythrocytes following hemorrhage into the ventricular system. Finally, ependymal cells have the structural and enzymatic characteristics necessary for scavenging and detoxifying a wide variety of substances in the CSF.

**Fig. 14-15 Ependymal and choroid plexus epithelial cells.** **A**, Ependymal cells are ciliated (*arrows*) and assist with the flow of cerebrospinal fluid (CSF) through the ventricular system. H&E stain. **B**, Choroid plexus epithelial cells (*arrows*) secrete CSF from a brush-border (microvilli) on the luminal surface. The surface of the choroid plexus also has cilia that occur singly or more often in groups of three or more on a single cell. H&E stain. (*A and B*, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

During embryonic development, the medial wall of the lateral ventricle (choroid fissure), the roof of the third ventricle, and the rostral part of the roof of the fourth ventricle consist of a single layer of neuroectoderm that is adherent on its outer surface to the pia mater. This neuroectoderm-pia union forms the tela choroidea, providing an anchor for the choroid plexuses, which is formed by an invagination of this bilayer membrane into the ventricular spaces.

Choroid plexus epithelial cells are modified ependymal cells. The choroid plexus epithelium is a single-layered, cuboidal to columnar, epithelium with a microvillus border (Fig. 14-15). CSF is secreted from the microvillus border. Choroid plexus epithelial cells, along with capillaries and the pia mater, form the choroid plexuses that project into the lateral, third, and fourth ventricles. The basic function of choroid

846

847

## Pathologic Basis of Veterinary Disease, 4th Edition

---

plexuses is to produce the CSF that fills the ventricular system and the subarachnoid space. CSF has two important functions: (1) to act as a “shock absorber” to mitigate the effects of trauma to the brain and spinal cord and (2) to deliver nutrients to and remove wastes from the CNS.

The normal flow pattern of CSF is regulated by an intraventricular biologic pressure gradient in which the pressure created by secretion of CSF exceeds the pressure created by its absorption in arachnoid villi (arachnoid granulations). Arachnoid villi are focal extensions of the arachnoid and subarachnoid space that extend into the dorsal sagittal venous sinus of the brain. CSF is secreted by the choroid plexuses in the lateral, third, and fourth ventricles. It should be noted, however, that fluid from other sources, such as secretion by the ependyma, interstitial fluid of the brain, and ultrafiltrate of the blood, has also been reported to contribute to the formation of CSF. It moves from the lateral ventricles into the third ventricle, from the third ventricle through the mesencephalic aqueduct (aqueduct of Sylvius in human beings), and then to the fourth ventricle. Once in the fourth ventricle, the CSF exits through the two lateral apertures of the fourth ventricle to enter the subarachnoid space. Lateral apertures are the two openings in the caudal medullary velum that forms the roof of the fourth ventricle into the subarachnoid space, one at each side of the cerebellopontine angle. Although the central canal of the spinal cord is connected to the ventricular system at the caudal end of the fourth ventricle, there apparently is little active movement of CSF within the central canal. CSF in the subarachnoid space is reabsorbed by the arachnoid villi in the brain. Recent evidence indicates that other routes of CSF drainage, in addition to arachnoid granulations, also exist and vary in different species. Venous sinuses, lymphatic drainage, and the cribriform plate appear to play important roles in CSF drainage and the maintenance of normal interventricular CSF pressure. In fact, experimental evidence suggests that the cribriform plate route may be the most important of the four. In human beings, the entire volume of CSF is circulated approximately four times a day; however, with aging, the entire volume of CSF circulates less than two times a day.

14.1.1.2.6

### MENINGES

The meninges, which enclose the CNS, consist of three layers: the dura mater (outermost layer [pachymeninges]), the arachnoid membrane (mater), and the pia mater (innermost layer) (Fig. 14-16). Together the arachnoid membrane and pia mater are frequently referred to as the leptomeninges, pia-arachnoid layer, or pia-arachnoid. The arachnoid membrane and pia mater are held together by bands of fibrous tissue called arachnoid trabeculae. This arrangement forms a compartment called the subarachnoid space in which CSF flows and which also contains blood vessels and nerves. There is also limited evidence based on studies in human beings with neuro-acquired immunodeficiency syndrome that the brain has a primitive lymphatic system. The leptomeninges form a protective covering for the CNS and provide an external envelope filled with CSF that provides additional protection.

The dura mater, once referred to as the pachymeninx (thick meninges), is a strong and dense collagenous membrane (Fig. 14-17). In the cranium, the dura consists of two layers that are fused with each other. The outer layer serves as the periosteum of the cranial bone, except in the areas of the venous sinuses (surrounded by dura) and falx cerebri, which is the longitudinal layer that extends ventrally between the two cerebral hemispheres. At the level of the foramen magnum, the two layers become separated; the outer layer continues to function as the periosteum of the vertebral (spinal) canal, and the inner layer forms the free dural membrane that surrounds the spinal cord. The inner aspect of dura mater is lined by elongated, flattened mesothelial-like cells. Except in neonates, there is no epidural (extradural) space in the cranial vault as there is in the spinal cord. There can be a “potential” epidural or extradural space in mature animals from hemorrhage caused by trauma.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The arachnoid consists of both the multilayered membrane composed of cells that overlap one another, and the trabeculae that join it to the pia. The arachnoid has tight junctions between its cells, although other junctions have also been described. It contains no blood vessels and has an outer smooth surface formed by mesothelial-like cells that abut similar cells in the dura mater. The mesothelium-like surfaces of the dura and arachnoid oppose and slide over each other, analogous to the parietal and visceral surfaces of other serous membranes.

The pia mater is closely adherent to the surface of the brain and spinal cord and is penetrated by a large number of blood vessels that supply the underlying nervous tissue (Fig. 14-18). The pia mater consists of flat, thin, overlapping connective tissue cells (fibroblasts) that are separated from the underlying neural tissue by variable amounts of loose collagen fibers and the glia limitans. In many areas the pia, which lacks a basal lamina, is only one-cell-layer thick and has fenestrations, so that the glia limitans is exposed directly to the subarachnoid space. Pia and arachnoid cells also ensheath blood vessels, collagen bundles, and nerves that are within or cross the subarachnoid space and also are around arteries that penetrate into the CNS up to 1 to 2 mm in depth. Macrophages also are present throughout the leptomeninges.

847

849

**Fig. 14-16 Organization of the meninges.** The meninges, from outside to inside, are the dura mater, arachnoid mater, and pia mater as illustrated in the diagram. The arachnoid mater and the pia mater form the leptomeninges. These two layers of the leptomeninges also enclose the subarachnoid space, which contains the arteries, veins, and nerves and is filled with cerebrospinal fluid. The pia mater is attached to the surface of the central nervous system. Astrocytes and their foot processes underlie the pia mater and form the glia limitans (*inset 1*) and surround the endothelial cells that form the blood-brain barrier. As arterioles penetrate the cortex to supply the tissue with blood, they carry the pia and glia limitans with them for 1 to 3 mm until the arteriole structurally becomes a capillary. At this transition site within the cortex, the capillary penetrates the pia and is surrounded by the glia limitans, and the end feet of the astrocytes become part of the blood-brain barrier (*inset 2*). Components of the blood-brain barrier are capillary endothelial cells, basement membrane, and astrocytic foot processes, but the barrier is formed structurally by tight junctions between endothelial cells and functionally by specialized transport systems in these cells. (*Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.*)

**Fig. 14-17 Layers of the meninges. A, Brain, dog.** The dura matter is a thick opaque layer. Here it covers the rostral (cranial) half of the brain and has been dissected away from the caudal half of the brain to expose the underlying leptomeninges. In old animals, the dura mater often fuses with the periosteum of the calvarium, and at necropsy to expose the brain, it is usually removed attached to the calvarium. The leptomeninges are present, but because they are so transparent, in this photograph they are barely visible on the surface of the caudal half of the brain between gyri. **B, Spinal cord, horse.** The dura matter is the thick opaque layer dissected from and lying to the right of the spinal cord. The leptomeninges (pia-arachnoid layer) are present (but not readily visible in this photograph) on the exposed surface of the spinal cord. Arrows indicate spinal nerve roots. (*A and B, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.*)

14.1.1.2.7

### ENDOTHELIUM

The basic functions of endothelium in the CNS are to line luminal surfaces of blood vessels; form the blood-brain barrier; regulate thrombosis, thrombolysis, and platelet adherence; and maintain a nonthrombogenic boundary between coagulation cascade molecules and luminal surfaces of endothelial

## Pathologic Basis of Veterinary Disease, 4th Edition

---

cells. Additionally, endothelial cells function as regulatory barriers to small and large molecules crossing the endothelium, and they control the adherence of leukocytes to their luminal surfaces. The endothelial cells of the blood-brain barrier actively transport those molecules that the brain consumes rapidly and in large quantities, such as glucose, amino acids, lactate, and ribonucleosides.

14.1.1.3

### GROUND RULES FOR UNDERSTANDING INJURY IN THE CENTRAL NERVOUS SYSTEM

Before the responses of the CNS to injury are discussed, some fundamental concepts are reviewed in [Box 14-2](#).

14.1.1.4

### RESPONSES OF NEURONS TO INJURY

Neurons are the most vulnerable cells in the nervous system and probably within the body. They have large requirements for energy to maintain normal metabolism, transport systems, and the formation of cytoskeleton proteins in the axon, which can extend over long distances (>1 m), but neurons lack adequate intracellular glucose reserves. Therefore they are completely dependent for survival on an adequate blood supply to provide glucose. Additionally, neurons are vulnerable to free radical oxidative stresses and have a limited ability to buffer shifts of calcium ions into the cell, which can interfere with oxidative phosphorylation and ATP production, such as occurs with ischemia.

Neurons are especially sensitive to excessive stimulation with excitatory amino acid neurotransmitters called excitotoxins, such as glutamate and aspartate. These neurotransmitters are also released in a wide variety of neuronal injuries, especially in neuronal ischemia. Under normal conditions, astrocytic processes surrounding synapses have efficient uptake systems to remove excitotoxins, and neurons are not injured. In excessive quantities, persistent binding of excitotoxins to receptors can lead to neuronal degeneration and death.

The microscopic appearance of the neuronal cell body can vary according to the injury. Characteristic changes of the neuronal cell body are reviewed in [Box 14-3](#).

14.1.1.4.1

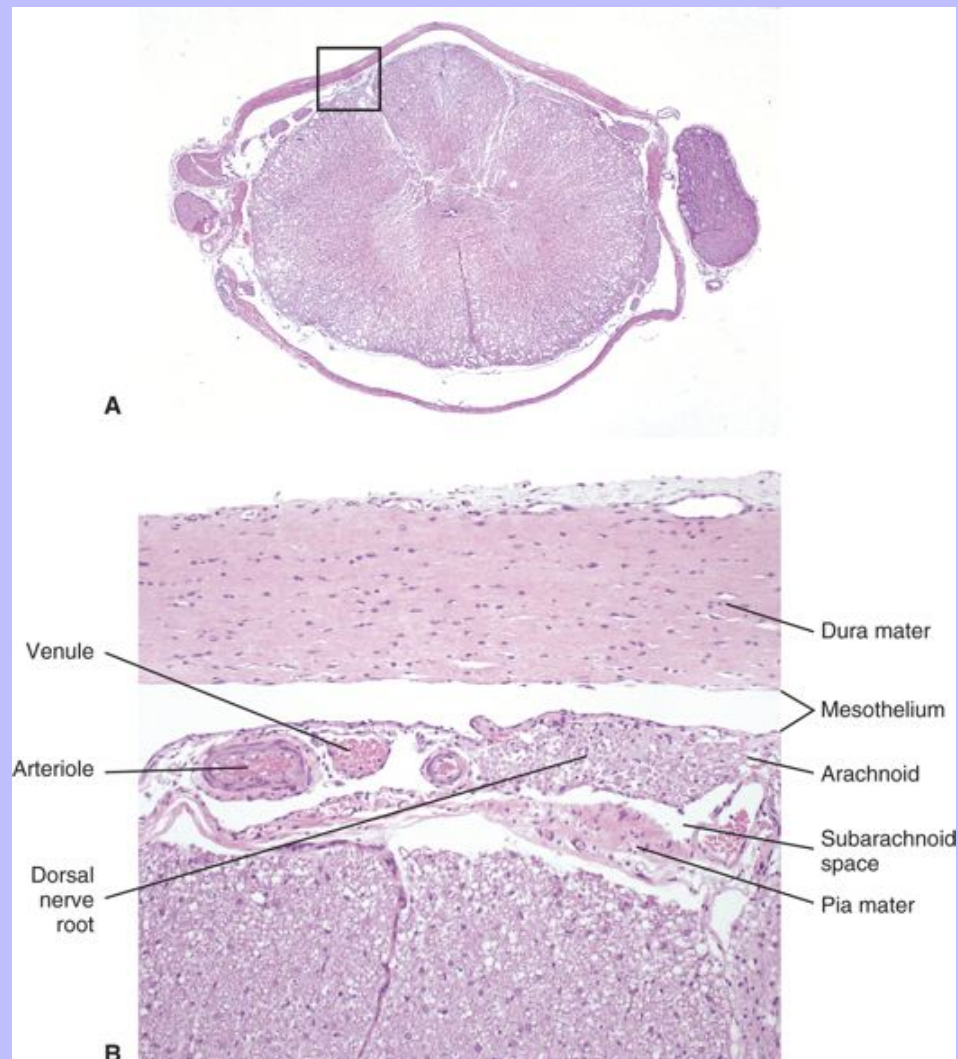

### NEURONAL CELL DEATH

Neurons can die following injury as a result of one of two mechanisms: apoptotic cell death and necrotic cell death. These mechanisms are summarized next and discussed in greater detail in [Chapter 1](#). Both apoptotic and necrotic neuronal cell death can occur concurrently or in temporal or spatial sequences within the nervous system. Although apoptotic and necrotic neuronal death represent different responses of neurons to injury, identical receptors, messenger systems, and mechanisms of cytotoxicity are likely involved in both apoptotic and necrotic cell death. Factors that determine whether the apoptotic or necrotic pathway is activated are unclear but appear to depend on the character of the initiating ligand or injury, type of cell membrane receptors activated, and caspases expressed in response to injury.

849

Zachary, College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

14.1.1.4.1.1

### Apoptotic Cell Death (Programmed Cell Death)

Apoptosis is a single cell-initiated, gene-directed cellular, self-destructive regulatory mechanism that leads to “programmed” cell death. This mechanism is used: (1) during the development of the nervous system to ensure proper migration and orientation of cell layers and removal of excess embryonic cells; (2) to remove “aged” cells (i.e., cell turnover) in organs; and (3) to maintain cell number homeostasis in organ systems that have regenerative capacity (endocrine glands).

Apoptotic neuronal death is characterized by a sequence of cellular degenerative steps that can be identified biochemically and morphologically. Following appropriate signals recognized and interpreted by cell membrane receptors (Fas, tumor necrosis factor [TNF] receptor-1, TNF-related apoptosis-inducing ligand receptors), a family of proteins known as caspases are activated. Caspases cleave cellular substrates that are required for cellular function and include cytoskeleton proteins and nuclear proteins, such as DNA repair enzymes. Caspases also activate other degradative enzymes such as DNAases, which cleave nuclear DNA.

The role of apoptotic neuronal death in specific neurologic diseases will be discussed in greater detail in subsequent sections. As examples, some viral infections that occur in utero produce developmental anomalies by initiating apoptosis that leads to faulty differentiation of embryonic granule and Purkinje cell layers, such as occurs in experimental Borna disease. Mild ischemia, excitotoxins, hormones, corticosteroids, and proinflammatory cytokines can induce apoptotic cell death. Rabies virus has been linked experimentally to apoptotic neuronal death.

850

851

14.1.1.4.1.1.1

### Box 14-2 Concepts in Understanding Responses of the Central Nervous System to Injury

1. The cells of the central nervous system (CNS) vary in their susceptibility to injury (neurons > oligodendroglia > astrocytes > microglia > blood vessels). Neurons are the most sensitive to injury, whereas glial and other cells are more resistant to injury.
2. Neurons have only small energy stores; therefore they are dependent on an intact blood flow to supply oxygen and nutrients, particularly glucose. Neurons with the highest metabolic rate, such as some neurons in the cerebral cortex, will die 6 to 10 minutes after the cessation of blood flow after cardiac arrest.
3. There is no regeneration of neurons. The neurons you have now are the ones you were born with; however, their metabolism is dynamic, and metabolites are continually turned over and replaced.
4. If nerve fibers in the CNS are cut by transection of the cord, no or little regeneration of nerve fibers results. Therefore if sufficient motor nerve fibers are cut, there is paralysis; if not, there is a neurologic deficit.
5. If fibers in the peripheral nervous system are cut, they can regenerate under certain circumstances. This outcome depends on axoplasmic flow, alignment of the proximal and distal portions of the nerve, and the preservation and alignment of the proximal and distal portions of the endoneurial tube (the structure in which the axon lies).

6. Healing in the CNS is different than in the rest of the body. There are few fibroblasts in the CNS and they are principally found only in the leptomeninges and in the outer few millimeters of the CNS, where they are pulled into the cerebral cortex with blood vessels. Therefore wounds deep in the CNS heal by proliferation of astrocyte processes. Astrocytic processes fill small dead spaces of less than a few millimeters and encapsulate large dead spaces and abscesses. Superficial wounds or wounds that extend through the leptomeninges heal by synthesis and deposition of collagen by fibroblasts (fibrous connective tissue) and by proliferation of astrocytic processes. However, in contrast to the fibroblast, astrocytic processes produce a very poor capsule, which can break down easily.
7. The cranial cavity is nearly filled by the brain, its coverings, and fluids. Therefore many lesions, such as tumors, abscesses, hemorrhages, and hydrocephalus in the brain, produce clinical signs because they are space-occupying lesions, which in neuropathology implies that they cause atrophy or displacement of portions of the brain or cord, depending on the duration of the injury.
8. The blood-brain barrier can exert control over drugs and antibodies from entering the intact brain. It is also a barrier to infection and is formed by the tight junctions of the endothelial cells, aided by basement membrane, and the end feet of the astrocytes, which lie on the outside of the capillary.
9. Although the CNS has the ability to resist infection and injury, once the CNS is infected, it has a low degree of resistance when compared with other tissues of the body. Microbes, such as *Cryptococcus neoformans*, which normally would be relatively nonpathogenic in other organs, may produce death if the CNS is infected. This outcome in part is attributable to the complexity of the CNS and the fact that it is the most vital organ in the body. Any disease process will often cause catastrophic results in the CNS, as opposed to tissues such as in the lung, liver, and kidney.

condensed cytoplasm is packaged for removal by macrophages. Inflammation is not induced by apoptotic cell death.

14.1.1.4.1.2

### Necrotic Cell Death

Necrosis is a process that usually affects groups of cells in contrast to single isolated cells as observed in apoptosis. Necrosis is characterized by the following sequence: hydropic degeneration, swelling of mitochondria, pyknosis and fragmentation of the nucleus, and eventual cell lysis caused by cell membrane damage and the inability of the plasma membrane to control ion and fluid gradients (see [Figs 1-11 through 1-17 in Chapter 1](#)). Cellular debris associated with necrotic neuronal death will illicit an inflammatory response in contrast to apoptotic neuronal death.

851

852

14.1.1.4.1.2.1

### Acute neuronal necrosis (ischemic cell change)

Acute neuronal necrosis is a common response to a variety of CNS injuries, such as cerebral ischemia caused by blood loss and hypovolemic shock, vascular thrombosis, and cardiac failure; inflammatory mediators; bacterial toxins; thermal injury; heavy metals; nutritional deficiencies, such as thiamine deficiency; and trauma. Additionally, conditions that reduce ATP generation through oxidative phosphorylation will also lead to neuronal degeneration and death. Such conditions include: (1) interference with cytochrome oxidase activity in mitochondria caused by cyanide poisoning; (2) competitive inhibition of oxygen uptake in carbon monoxide poisoning; and (3) inadequate availability of glucose for neuronal metabolism in hypoglycemia.

The susceptibility of cells and tissue structures of the CNS to ischemia, in decreasing order of susceptibility, are neurons, oligodendroglia, astrocytes, microglia, and blood vessels. However, within groups of neurons, some neurons are more sensitive to injury than others. This phenomenon is called selective neuronal vulnerability. Purkinje cells, some striatal neurons, neurons of the third, fifth, and sixth cerebral cortical lamina, and hippocampal pyramidal cells have the highest vulnerability. A regional vulnerability of neurons has also been reported (cerebral cortex and striatum > thalamus > brain stem > spinal cord). It is hypothesized that the most vulnerable neurons likely produce the most excitotoxins, such as glutamate, and are the most sensitive to them. Because of the microanatomic arrangement of the cerebral cortex, ischemic neurons often occur in a laminar pattern within the cerebrocortical gray matter. This microanatomic pattern accounts for the laminar lesions observed in thiamine deficiency-induced polioencephalomalacia in ruminants and in other diseases, such as salt poisoning in pigs and lead poisoning in ruminants.

Following the various types of CNS injury, there is an early increase in ATP-dependent release of normally sequestered intracellular calcium ions from altered mitochondria and endoplasmic reticulum. Also during this time, neuronal depolarization potentiates the release of the neuroexcitatory neurotransmitter glutamate. Persistent activation of glutamate receptors of target cells results in a disturbance referred to as excitotoxicity. This altered activity leads to a notable influx of extracellular calcium into cells, causing further impairment of mitochondrial function and the generation of reactive oxygen species, such as superoxide, hydrogen peroxide, hydroxyl radicals, and nitric oxide. These reactive oxygen species, exerting their effects especially on lipid-rich cell membranes, can enhance the existing excitotoxicity, cause further influx of calcium into cells as a result of membrane damage, and ultimately result in neuronal dysfunction and death. Additionally, reperfusion of ischemic tissue after the initial ischemic injury can enhance the generation of reactive oxygen metabolites, thus amplifying the tissue damage. Other influencing factors include the

## Pathologic Basis of Veterinary Disease, 4th Edition

---

temperature of the brain at the time of ischemia, with lower temperatures (as little as 2° C decrease) having a sparing effect and elevated temperatures having an enhanced effect on neuronal injury following ischemia.

Neurons are dependent on a continuous supply of oxygen to remain viable and if the supply is interrupted for several minutes, the vulnerable neurons as described previously will degenerate. Ischemic cell change can also result from metabolic disturbances other than ischemia, such as in thiamine deficiency and cyanide toxicosis, which interferes with oxygen use. In H&E stained sections, the cytoplasm of the neuronal cell body is shrunken, deeply eosinophilic, and frequently sharply angular to triangular in shape (Fig. 14-19). The nucleus is reduced in size, is often triangular, and is pyknotic. The nucleolus and Nissl substance are usually not detectable. Ischemia neurons die and are removed either by a process called neuronophagia, which is phagocytosis by microglial cells and macrophages or by lysis (Fig. 14-19). Following neuronal necrosis, there is swelling of perineuronal and perivascular astrocytic processes.

14.1.1.4.2

### CHRONIC NEURONAL NECROSIS (BRAIN ATROPHY)

Neuronal death and loss of neurons can occur as a result of progressive disease processes of long duration in the CNS. This loss, termed simple neuronal atrophy, is seen with slowly progressive neurologic diseases, such as cerebral cortical atrophy of aging, ceroid-lipofuscinosis, and primary and multisystem and cerebellar neuronal degeneration. Gross lesions are usually not visible, but when cerebrocortical neurons die, there can be atrophy of cerebral gyri, which results in widening of the sulci (Fig. 14-20). Microscopic lesions indicative of an earlier loss of neurons are diminished numbers of neurons and astrogliosis and atrophy and loss of neurons in functionally related systems. Loss of neurons over time results in progressively worsening neurologic dysfunction.

14.1.1.4.3

### WALLERIAN DEGENERATION AND CENTRAL CHROMATOLYSIS

Injury to axons of the CNS and PNS can result from a variety of causes such as: (1) traumatic transection 852  
leading to Wallerian degeneration; (2) compression and crushing; (3) therapeutic neurectomies; (4) nerve 853  
stretching injury; and (4) intoxication.

Fig. 14-19 **Neuronal necrosis (acute), so-called ischemic cell change, cerebrum, dog.** **A**, Neuronal ischemia. Neuronal cell bodies of cerebral cortical laminae are red, angular, and shrunken (*arrows*) and their nuclei are contracted and dense. This lesion can be caused by neuronal ischemia. H&E stain. **B**, Neuronophagia. This necrotic neuron cell body is surrounded by macrophages that will phagocytose the cell debris. H&E stain. (*A*, Courtesy Dr. J. F. ### Wallerian Degeneration

In 1850 Dr. Augustus Volney Waller described the pattern of microscopic lesions (necrosis) in axons and myelin sheaths following transection. These changes are characteristic of Wallerian degeneration (Fig. 14-21). Although Waller described this process in peripheral nerves, the term *Wallerian degeneration* is also used to describe necrosis that occurs in nerve fibers in the CNS after axons are injured (compressed or severed). The reactions of axon and myelin distal to the site of injury are to swell and break, and the rate is proportional to the diameter of the fiber. Thus the larger the diameter of the axon, the faster the rate of Wallerian degeneration.

Wallerian degeneration in the CNS follows the same sequence of events as in peripheral nerve fibers, but the speed of degeneration and phagocytosis is slower and there is little or no regeneration. In addition, an axon of the PNS has the advantage of: (1) efficient phagocytosis with removal of debris, (2) Schwann cells to remyelinate the regenerated axon, and (3) an endoneurial tube to guide the axon as it extends into the distal segment. On the other hand, an axon of the CNS has: (1) few microglia (sparse in the white matter) to remove myelin debris and (2) oligodendrocytes with a more limited capability to remyelinate axons. In the CNS, severed axons have a very limited ability to regenerate and successfully reinnervate their appropriate sensory or motor structures. In the PNS, if the severed nerves have a large distance between the cut ends, fibrous tissue scarring can prevent the axons from the proximal segment entering the distal endoneurial tubes and thus prevent the reparative response, resulting in the formation of a neuroma. If the severed ends of nerves are sewn together but the endoneurial tubes are malaligned, which usually occurs, the sensory and motor nerves will regenerate but reinnervate inappropriate sensory and motor structures.

853

855

Fig. 14-21 Peripheral nerve degeneration and regeneration (also applicable to neurons within the central nervous system).  
(Modified from Kierszenbaum AL: Histology and cell biology, St Louis, 2002, Mosby.)

The sequence of Wallerian degeneration in the PNS (similar in CNS except for significant regeneration; see previously) includes the following:

1. Degeneration and fragmentation of axon and myelin within several days. Proximal segment degenerates back to the next node of Ranvier, but all the distal segment dies.
2. Removal of axonal and myelin debris by phagocytosis. Some phagocytes are from the blood and some phagocytosis is by Schwann cells. All of the debris is cleared out of the endoneural tube within a few weeks.
3. Regeneration of axon if the endoneurium is intact to allow the axon of the proximal segment to enter and slide down the tube.
4. Remyelination by Schwann cells.

Microscopically, another early lesion in Wallerian degeneration is central chromatolysis, characterized by swelling of the neuronal cell body, dispersion of centrally located Nissl substance, and peripheral displacement of the nucleus (Fig. 14-22). The time of onset depends on how much of the axon has been lost, and thus on how close to the neuronal cell body the axon has been transected. Onset can begin within 24 to 48 hours and reach its maximum in about 18 days following axonal injury. The dispersal of Nissl substance (chromatolysis) is indicative of enhanced synthesis of transport and structural proteins required for regeneration of the axon and reestablishment of fast and slow axonal transport systems. The extent to which chromatolysis develops is related to the degree and location of axonal injury. It is more prominent and can even be followed by neuronal death, the more severe the loss of the volume of the axon and the closer the axonal injury is to the cell body. The time required for recovery of cell bodies can be several months and in most cases will vary from 3 to 6 months, depending on the severity of the axonal injury and the length of axon regenerated.

The change in the axon distal to the point of injury is first evident within 24 hours of injury. Wallerian degeneration is initially characterized by irregularity of the axonal diameter, which is followed after 48 to 72 hours by fragmentation of the axon and myelin along its length (Fig. 14-23). This axonal alteration is followed by disintegration, and usually there is no evidence of the axon remaining by the second week after the injury.

Changes in the myelin sheath surrounding myelinated axons are evident by 28 to 96 hours after injury when axonal disintegration is well advanced. Initially, there are irregularities in the sheath accompanied by folding, lamellar splitting, fracturing, and fragmentation (secondary demyelination). The fragmented myelin can form droplets (termed ellipsoids), which surround and enclose isolated fragments and debris of the former axon. Both axonal and myelin debris are then removed by macrophages through phagocytosis. Degeneration of myelin is usually completed by the end of the second week, although evidence of myelin debris can be detected up to 1 to 3 months after axonal injury (the time required for macrophages in the PNS to phagocytose and clear the debris). Myelin debris can be detected in the CNS (when compared with the PNS) for a much longer time after injury.

855

856

Fig. 14-22 **Central chromatolysis, neuron cell body, dog.** Compare with Figs. 14-4, *B* and 14-10. Affected neurons have eccentric nuclei and pale central cytoplasm with dispersed Nissl substance (*arrows*). (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 14-23 Wallerian degeneration, transverse section of spinal cord, dog.** Laceration and/or severe compression of myelinated nerves cause a specific sequence of structural and functional changes in the axon and the myelin (distal from the point of injury), referred to as Wallerian degeneration ([Fig. 14-21](#)). Axons are initially swollen (*arrows*) and are eventually removed by phagocytosis to leave clear spaces, which were once the sites of nerve fibers. The cell bodies of affected neurons usually have central chromatolysis, but are metabolically active in an attempt to regenerate the lost portion of the axon (not shown; see [Fig. 14-22](#)). (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

If the neuronal cell body survives the injury to its axon, regeneration from the proximal stump in the PNS can occur. The degree of axonal regeneration depends on the status of the endoneurial tube (sheath) distal to the original point of injury ([Fig. 14-21](#)). The normal endoneurial tube (sheath) and its contents consist (from outside inward) of (1) a connective tissue investment referred to as the endoneurium, (2) the basement membrane that surrounds the Schwann cells plus the Schwann cell cytoplasm, (3) the myelin sheath of myelinated axons, and (4) the axon. Approximately 24 to 72 hours after axonal injury, the endoneurial tube (sheath), formed by persisting basement membrane and endoneurium, contains degenerating remnants of the previously existing axon along with Schwann cells. Schwann cells begin to proliferate and eventually form a longitudinal column of cells referred to as the bands of Büngner.

If the endoneurial tube (sheath) remains intact, as can occur following a compression injury to a peripheral nerve, neural regeneration through the formation of axonal sprouts can occur. A regenerating

## Pathologic Basis of Veterinary Disease, 4th Edition

---

sprout from the proximal axonal stump can enter the column of Schwann cells and regenerate uninterrupted along its original pathway to the periphery, reestablishing innervation with an end organ (skeletal muscle). Such axons then become remyelinated and regain their physiologic function of impulse transmission. Because of axoplasmic flow, a regenerating neuron lengthens at a rate of approximately 1 to 4 mm/day. Although the time required for axonal regeneration can vary depending on the length of axon to be regenerated, examples of times required for morphologic and functional recovery following crush injury of a peripheral nerve are 250 to 300 and 456 to 486 days, respectively. If, however, the integrity of the endoneurial tube (sheath) is destroyed, as would occur after complete severance of a peripheral nerve, regeneration might not occur, because the proximal axonal stump might be prevented from reaching the distal endoneurial tube (sheath) by proliferated fibrous connective tissue (scar formation) at the site of axonal severance. Regenerating axons may also enter inappropriate endoneurial tubes (sheaths), resulting in improper impulse transmission, such as a sensory neuron axonal sprout entering an endoneurial tube intended for a nerve innervating a muscle.

The microscopic lesions for Wallerian degeneration within the CNS are similar to those described for the PNS, except that in the CNS, degenerated axons and myelin sheaths can remain for months to years before complete removal. With injury to the CNS, some cell bodies have central chromatolysis; others initially have central chromatolysis followed by atrophy and death. Affected axons and their myelin sheaths undergo a rather characteristic series of changes as they degenerate. Initially, axons form linear and bulbous swellings at, and some distance from, the site of injury. These enlargements are termed axonal spheroids. Spheroids consist of neurofilaments, microtubules, and cellular organelles. Because injury to the axon results in dysfunction of axoplasmic flow, any disruption of anterograde and retrograde axonal transport results in the accumulation of neurofilaments, microtubules, cellular organelles, and recycled molecules at or near the point of injury. This process occurs in peripheral nerves as well.

The axonal enlargements can be seen as early as a few hours at the site of injury and remain prominent, particularly for the first week or so (Fig. 14-23). The surrounding myelin sheath is usually distended to create a space between the sheath and the axonal swelling. Progressively, such affected axons and myelin sheaths fragment along their length, forming ellipsoids as in the PNS. Eventually ellipsoids are removed through degeneration and phagocytosis, leaving an empty space, or one still containing myelin debris and macrophages (gitter cells). The latter is termed a “digestion chamber.” With time and continued lysis and phagocytosis of the debris, most of the lesion will consist of enlarged empty spaces. The absence of swollen axons in such dilated spaces, especially in the early stages after CNS trauma, does not necessarily mean that the entire axon has degenerated and been removed, which can require several months. It might instead be the site of separation of an enlarged axon from the adjacent axon at the level of the section being examined.

### 14.1.1.5 RESPONSES OF MACROGLIA TO INJURY

#### 14.1.1.5.1 ASTROCYTES

Common astrocytic reactions in CNS injury are swelling, hypertrophy, division, and the laying down of intermediate filaments in cell processes. The term *astrocytosis* means that astrocytes have increased in size and number in response to injury, whereas the term *astrogliosis* (somewhat synonymous with hypertrophy) implies synthesis of intermediate filaments and an increased length, complexity, and branching of the astrocytic processes. The recognition of these differences is based on histopathologic evaluation.

Swelling is an acute response and is reversible, or it may progress with time to hypertrophy. Swollen astrocytes have clear-staining or vacuolated cytoplasm. Astrocytes swell following ischemia because of the increased uptake of sodium, chloride, and potassium ions and water in an effort to maintain

856

homeostasis in the extracellular microenvironment. It is important to remember that such swelling depends on the astrocyte being viable and still having a semipermeable plasma membrane, even though its function may be altered. With progression, and if the degree and duration of ischemia are sufficiently severe to result in cell death, the plasma membrane becomes fully permeable, and the cell does not swell but becomes shriveled or shrunken and undergoes disintegration, as described for the ischemic cell change of neurons.

857

If injury is severe, astrocytic processes fragment and disappear followed by lysis of the cell body. Hypertrophied astrocytes often referred to as “reactive,” represent a response to a milder and more protracted injury to the CNS. Because of increases in intermediate filaments, mainly GFAP, the cytoplasm becomes apparent along with increased length and branching of the processes with H&E staining. The increase of intermediate filaments and consequently the intensity of GFAP immunohistochemical staining in these cells are so dramatic that some have defined reactive astrocytes on the basis of this change. In protracted degenerative conditions, astrocytes termed gemistocytes can be observed (Fig. 14-24). These cells have eccentric nuclei and abundant pink homogeneous cytoplasm, in contrast to the lack of visible cytoplasm in normal astrocytes, with routine H&E staining. Animals with hepatic encephalopathy can have a unique microscopic lesion in the brain affecting astrocytes of the cerebral cortices. Astrocytic nuclei tend to be in pairs occasionally with prominent central nucleoli and surrounded by a clear space which is the edematous cytoplasm. They are called Alzheimer's type II astrocytes (Fig. 14-13, D).

Astrocytic proliferation can occur in CNS injury, but in most instances proliferative capacity is limited. When it occurs, the most dramatic examples are associated with attempts by reactive astrocytes (astrogliosis) to “wall off” abscesses and neoplasms or to fill in cavitated areas that result following lysis of necrotic neurons with the processes of astrocytes. This laying down of glial fibers is referred to as a glial scar. It is formed by a network of interlaced astrocytic processes and provides a loose barrier that separates the injured brain from the more normal adjacent tissue. This astroglia-fibroblast interface in injured CNS attempts to reform the glia limitans, restore the blood-brain barrier, and reestablish fluid and electrolyte balances.

### 14.1.1.5.2

#### OLIGODENDROCYTES

Oligodendroglia react to injury by cell swelling, hypertrophy, and degeneration. Both perineuronal and interfascicular oligodendroglia can swell, hypertrophy, and degenerate; however, only oligodendroglia precursor cells can proliferate to replace degenerate cells. The role that perineuronal or satellite oligodendroglia play in normal neuronal function and neuronal injury has not been definitively clarified. Microscopically, these cells swell and hypertrophy around injured neurons, and this response to injury has been called satellitosis (Fig. 14-13).

**Fig. 14-24 Gemistocytes (gemistocytic astrocytes), cerebrum, dog.**

When astrocytes react to injury, initially by hypertrophy and later by the synthesis of increased glial filaments (astrogliosis), the nuclei enlarge and often the cell body, which is not normally visible in H&E stained sections, will become visible. These astrocytes are called gemistocytes (plump astrocytes) (*arrows*). They occur in diseases in which there is alteration of intracellular and extracellular fluid balances or injury to the parenchyma, where healing will be by glial scarring (astrogliosis, e.g., to encapsulate a deep abscess or fill in a small area of dead space). H&E stain. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

Degeneration of interfascicular oligodendroglia caused by ischemia, certain viruses, lead toxicity, and autoimmunity can result in selective degeneration of myelin sheaths referred to as primary demyelination. Primary demyelination is the loss of myelin around an intact axon. Mechanisms of primary demyelination are summarized in [Box 14-4](#). Protracted or repetitive injury to myelinating cells and their myelin sheaths can lead to irreversible neuronal atrophy. Oligodendroglia precursor cells located in the subventricular zone of the CNS can mature into interfascicular oligodendroglia and can also proliferate in response to noncytotoxic injury and become involved in remyelination following primary demyelination.

CNS or PNS injury can also lead to loss of myelin secondary to injury of the axon and its cell body or to death of the neuron. When axons are injured, myelin lamellae forming the internodes are retracted and removed by phagocytosis. In some instances oligodendroglia or Schwann cells, the myelin-forming cells in the PNS, also degenerate. This form of myelin degeneration is termed secondary demyelination and is secondary to axon degeneration or loss (resembles Wallerian degeneration).

857

14.1.1.5.2.1

### Box 14-4 Mechanisms of Primary Demyelination

1. Inherited enzyme defects resulting in formation of abnormal myelin

Leukodystrophies in man and animals

2. Impairment of myelin synthesis and maintenance

Infection

Mouse hepatitis virus in mice and progressive multifocal leukoencephalopathy in humans; in both cases oligodendrocytes are selectively destroyed by viral agents and myelin cannot be maintained.

Nutritional

Lack of maintenance of myelin are due to copper deficiency, malnutrition, vitamin B<sub>12</sub> deficiency.

Toxins

Cyanide poisoning

Cuprizone toxicity

3. Loss of myelin as a consequence of cytotoxic edema (status spongiosis)

Hexachlorophene poisoning, usually prolonged edema

4. Destruction of myelin by detergent-like metabolites

Lysolecithin, a metabolite of phospholipase A (normally present in the nervous system) may destroy myelin.

14.1.1.5.3

### EPENDYMAL CELLS

Ependymal and choroid plexus epithelial cell responses to injury include atrophy, degeneration, and necrosis. Atrophy usually occurs in response to enlargement of the ventricles as occurs with hydrocephalus. The cilia and microvilli of affected cells are reduced in number, and there is also a reduction in their cellular organelles, such as endoplasmic reticulum and mitochondria. An additional lesion that accompanies ventricular enlargement is stretching and tearing of the ependymal lining. In such instances the resulting areas of ependymal discontinuity result in the subependymal CNS being directly exposed to the CSF. Unfortunately, mammalian ependymal cells do not regenerate and therefore do not repair the denuded areas. After 1 to 2 weeks, astrogliosis, which varies greatly in degree and uniformity, occurs in the exposed areas. Astrogliosis can extend into the ventricular space or be minimal in extent and confined to the periventricular area. Periventricular interstitial edema, myelin loss, and axon loss can ensue.

**Fig. 14-25 Glial nodule, brain stem, dog.** These nodules (*center*), formed by reactive microglial cells and macrophages, occur most frequently in viral encephalitides. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Inflammation of the ependyma, called ependymitis, can also occur, with infection being the most common cause. Microbes most commonly gain entrance to the ependyma via the circulation by lodging in the choroid plexuses, by direct contamination from a rupture of a cerebral abscess into the ventricular system,

## Pathologic Basis of Veterinary Disease, 4th Edition

and by retrograde reflux through the lateral apertures of infected CSF from the subarachnoid space in cases of leptomeningitis. In the case of bacterial infection, the suppurative exudate that forms in the CSF can cause obstructive hydrocephalus, although the development of hydrocephalus cannot always be explained on the basis of obstruction.

14.1.1.6

### RESPONSES OF MICROGLIA TO INJURY

Microglia are often the first cells in the CNS to react to injury, and the magnitude of the response is graded to correlate with the severity of damage. The responses of microglia to injury include hypertrophy, hyperplasia, phagocytosis of cellular and myelin debris, and neuronophagia, the removal of dead neuron cell bodies. After injury, microglia progress through a stage of activation, becoming fully immunocompetent reactive cells. These reactive cells readily proliferate, either focally, forming glial nodules (Fig. 14-25), or more diffusely, depending on the nature of the injury. As mentioned, in concert with astrocytes and neurons, microglia help coordinate inflammatory events in the CNS. Resident microglia and blood-derived macrophages express MHC class I and II antigens, serve as antigen-presenting cells, and possess a broad armament of adhesion molecules, cytokines, and chemokines. Once activated, these cells can also produce nitric oxide, reactive oxygen intermediates, and other chemical mediators of inflammation that can damage the CNS if not under strict control. When tissue necrosis occurs, macrophages derived from blood monocytes phagocytose the lipid-laden debris of dead neurons and glia, and they become foamy macrophages termed “gitter cells” (Fig. 14-26) and accumulate in the damaged CNS.

858

859

**Fig. 14-26 Gitter cells, cerebrum. A,** Early polioencephalomalacia, cow. Note the angular, eosinophilic neurons with pyknotic nuclei (ischemic cell change). Monocytes (*arrows*) in the perivascular space have been recruited from the vasculature. These cells will become macrophages and phagocytose cellular debris from the necrotic neurons and the myelin from the nerve fibers undergoing degeneration following the death of their neurons. Microglia also participate in this phagocytic response. Macrophages, which have ingested degenerate myelin or other cellular debris, have foamy cytoplasm and are termed gitter cells. H&E stain. **B,** Old necrotic area, dog. The normal brain parenchyma has liquefied and the debris has been ingested by macrophages (*arrows*), which has resulted in the cytoplasm of these cells becoming foamy. They are now designated as gitter cells or simply, foamy macrophages. (**A and B,** Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

### 14.1.1.7 RESPONSES OF THE MENINGES TO INJURY

Pathologic processes that initially involve the meninges, most commonly the leptomeninges, can secondarily invade the CNS because of the close apposition between the two tissues. Conversely, processes that primarily affect the CNS can secondarily affect the meninges, most commonly the leptomeninges.

*Meningitis* refers to inflammation of the meninges. In common usage, the term generally refers to inflammation of the leptomeninges in contrast to inflammation of the dura mater, which is referred to as pachymeningitis. Leptomeningitis can be acute, subacute, or chronic and, depending on the cause, suppurative, nonsuppurative, or granulomatous, and the exudate and inflammatory cells are chiefly in the subarachnoid space. Besides retrograde axonal transport, as occurs with, for example, *Listeria monocytogenes*, infectious agents spread to the meninges hematogenously by direct extension or by leukocytic trafficking.

Other meningeal lesions include: (1) inflammation of the external periosteal dura following osteomyelitis, formation of extradural abscesses, and skull fracture and involve the inner dura as an extension of leptomeningitis; and (2) proliferation of the inner dural mesothelial cells, arachnoid cells, fibroblasts, and cells of the pia mater in response to irritation. Additional lesions likely related to aging or degeneration include formation of cellular nests of mesothelial-like cells on the outer surface of the arachnoid membrane, mineralization of the arachnoid membrane in human beings, and mineralization plus ossification of the dura mater of the spinal cord in both human beings and dogs. Dural ossification in the dog, which tends to affect the ventral, cervical, and lumbar dura mater, is most commonly encountered in large breeds, although smaller breeds can be affected. The clinical significance of this lesion has been debated but not decided.

### 14.1.1.8 RESPONSES OF THE CIRCULATORY SYSTEM TO INJURY

#### 14.1.1.8.1 ENDOTHELIAL CELL (AND BLOOD VESSEL) RESPONSES TO INJURY

Because many of the infectious and neoplastic disease processes demonstrated in this book are spread through the body via the circulatory system, endothelial cells lining blood vessels, especially capillaries, are subject to a variety of injuries. Bacterial hematogenous CNS diseases occur at the interface between the white and gray matter in the cerebral hemispheres. This phenomenon is thought to result from abrupt changes in vascular flow or luminal diameter of vessels at the interface. These changes may make endothelial cells more susceptible to injury, vasculitis, and thrombosis or predispose the vessels for entrapment of tumor or bacterial emboli.

Endothelial injury can be reversible or nonreversible resulting in necrosis. Injury resulting in endothelial dysfunction can include the activation and release of vasoactive mediators, such as histamine, leading to local and/or systemic changes in vascular flow, pressure, and permeability. Bacterial products and elicited inflammatory cytokines can directly or indirectly cause vascular inflammation (vasculitis) leading to thrombosis and disseminated intravascular coagulation. Thrombotic meningoencephalitis of cattle caused by the bacterium *Histophilus somni* (formerly *Haemophilus somnus*) is an example of this type of injury (Fig. 14-27). Certain herpesviruses and protozoa can also infect endothelial cells and cause endothelial necrosis with vasculitis, hemorrhage, and thrombosis. Finally, some pathogens, such as angioinvasive *Mucor* spp., directly invade blood vessels, resulting in necrosis of the endothelium. Vasculitis resulting in thrombosis can cause tissue ischemia, infarction, and vasogenic edema of the affected area of the CNS. A review of endothelial injury can be found in [Chapter 2](#).

### 14.1.1.8.2

#### INFARCTION

*Infarction* means necrosis of a tissue following obstruction (ischemia) of its arterial blood supply. The rate at which ischemia occurs in the CNS determines the degree of injury that follows. The more rapid the onset of ischemia, the more severe the lesion. However, if the obstruction is sudden, as caused by an embolus, many of the neurons can die within minutes and other components within hours. This outcome also applies to compressive injuries to the CNS that produce a sudden reduction in blood flow, such as can happen with sudden compression in rapidly occurring Hansen type I disk herniation in the dog. If the blood flow through an artery is gradually reduced, for example because of arteriosclerosis, there is often sufficient time for anastomotic vessels to dilate and compensate. Anastomoses of the arteries that penetrate from the ventral and cortical surfaces of the brain are insufficient to prevent infarction following sudden occlusion of one or more of these arteries. If the compression is slow—such as is caused by a slowly developing Hansen type II disk herniation in a dog or by a slowly growing neoplasm from the exterior, such as meningioma in a cat—adjacent neural tissue will atrophy to accommodate the mass.

Cerebral necrosis, comparable to infarction following vascular occlusion, can also result from other causes, including cessation of cerebral circulation caused by cardiac arrest, sudden hypotension caused by reduced cardiac output, and reduced or absent oxygen in inspired air. Additional causes include altered

## Pathologic Basis of Veterinary Disease, 4th Edition

---

function of hemoglobin as a result of carbon monoxide poisoning, inhibition of tissue respiration following cyanide poisoning, toxic substances and poisons, and nutritional deficiencies.

When an artery supplying the CNS is suddenly occluded, blood supply to cells at the center of the infarcted area is rapidly stopped, and if maintained for a sufficient period, all cells die. Neurons at the border of this area continue to receive some blood from nonobstructed vessels. It is proposed that the axonal terminals of degenerated ischemic neurons in the center of the infarct release excessive amounts of the neurotransmitter glutamate, causing injury to still-viable neurons in the borders, which increases the extent of the infarct. This process begins following the binding of the neurotransmitter glutamate to receptors on viable neurons in the borders, inducing an abnormal movement of calcium ions into the recipient cells followed by an increase in intracellular calcium ion concentration. This buildup of calcium ions contributes to a multifunctional cascade that leads to neuronal death. When there is hemorrhage with the infarct, the mechanical injury from the pressure, plus tissue displacement by the hemorrhage, can cause additional damage. See [Table 14-1](#) for the reparative responses associated with the resolution of infarcts.

860

861

Areas of cerebral infarction differ somewhat in gross appearance from infarcts in other tissues ([Fig. 14-28](#)). The abundance of lipids and enzymes, plus the relative lack of fibrous connective tissue stroma in the brain and spinal cord, results in the affected areas eventually becoming soft because of liquefaction necrosis. The gross appearance of infarction may also differ according to location. Lesions affecting the gray matter tend to be hemorrhagic, whereas infarction of the white matter is often pale. This difference is probably due in part to the less dense capillary meshwork in the white matter, and in part to the fact that the vessels supplying the white matter have fewer anastomoses than those of the gray matter. Infarcted tissue goes through a characteristic sequence of changes that can permit a relatively accurate determination of the age of the infarct. An outline of the chronologic events that occur after an ischemic episode that lasts more than 5 to 6 minutes and is followed by resuscitation of an animal is given in [Table 14-1](#). As can be seen, the tissue changes listed in [Table 14-1](#) take different periods of time to develop in the living resuscitated animal after ischemia occurs. Variation in the times that specific lesions occur depends on the extent and duration of the initial ischemic event. Following removal of cellular and myelin debris, the infarct is repaired by astrocytes. If the infarct is small (<1 mm), it is filled via astro-gliosis; if the infarct is larger, it is encapsulated to form a cyst.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 14-1 Chronologic Sequence of Changes within Infarcted Tissue (in the Living Animal) following an Ischemic Event

Ischemic Event	Time Following Tissue Change
Immediate (seconds)	Cessation of blood flow (ischemia) and accumulation of waste products
Few minutes	Cellular injury and death; coagulation necrosis and edema; hemorrhage (especially in gray matter)
20 min	First microscopic evidence of neuronal injury (perfusion-fixation)
1–2 hr	First microscopic evidence of neuronal injury (immersion fixation)
2 hr	Pale staining of infarct microscopically (white matter); swelling of capillary endothelium; increase in size of astrocytic nuclei
3–5 hr	Ischemic cell change in most neurons; swelling of oligodendroglia and astroglia; beginning clasmotodendrosis of astrocytes
6–24 hr	Beginning neutrophilic infiltration; alteration of myelin (pale staining), 8–24 hours; degeneration and decrease of oligodendroglia, 8–24 hours; astrocytic swelling and retraction and fragmentation of processes (clasmotodendrosis), and degeneration <sup>*</sup> ; cytoplasm of astrocytes visible, 8–24 hours <sup>*</sup> ; vascular degeneration and fibrin deposition, 8–24 hours; thrombosis <sup>†</sup> , 6–24 hours; beginning endothelial proliferation at margin of infarct, 9 hours
8–24 (up to 48) hr	Initial gross detection of infarct unless hemorrhagic; infarct edematous (swollen), soft, pale, or hemorrhagic and demarcated
1–2 days	Swelling of axons and myelin sheaths; prominent neutrophilic infiltration
2 days	Prominent loss of neuroectodermal cells; continued proliferation of endothelial cells; reduced number of neutrophils; beginning increase in mononuclear cells (gitter cells)
3–5 days	Prominent number of mononuclear cells (gitter cells); disappearance of neutrophils; continued endothelial cell proliferation; number of capillaries appear increased; beginning of astrocytic proliferation (often at margin of infarct)
5–7 days	Grossly, swelling of infarct reaches maximum
8–10 days	Reduction in gross swelling of infarct; liquefaction necrosis; prominent number of mononuclear cells (gitter cells); continued endothelial cell proliferation; beginning fibroblastic activity with collagen formation, variable but most prominent in central nervous system tissue adjacent to the meninges; beginning increase of astroglial fiber production, 5–13 days
3 wk–6 mo	Mononuclear cells decreased; astroglial fiber density increased (especially at margin); astrocytic proliferation reduced; astrocytes return to original appearance; cystic stage of infarct, 2–4 months; vascular network may be present within cyst; endothelial cell proliferation reduced

\* The degree of astrocytic injury will depend on location (e.g., central or peripheral) of the cells within the infarct.

† Obviously, thrombosis may occur earlier than 6 hours. This is the time when it may initially be prominent.

861

**Fig. 14-28 Central nervous system infarct, brain, thalamus, dog.** A focal, sharply demarcated area of yellow discoloration and malacia (softening) (arrow) in the left central thalamus is most likely an infarct. Scale bar = 2 cm. (Courtesy Dr. R. Storts, College of Veterinary Medicine, Texas A&M University.)

### 14.1.1.9 CENTRAL NERVOUS SYSTEM SWELLING AND EDEMA

#### 14.1.1.9.1 CONGESTIVE BRAIN SWELLING

Congestive brain swelling, as distinguished from cerebral edema, is thought to represent, at least in part, an unregulated vasodilation following trauma, and it can cause serious brain damage (even more severe than the primary injury) if not properly controlled. This lesion therefore represents an enlargement of the brain resulting in elevated intracranial pressure caused by the increased diameter of the blood-containing vasculature, whereas edema results in an increased pressure following accumulation of fluid in the interstitium or intracellularly outside the circulation. Acute brain swelling can be localized (usually of lesser significance) when associated with focal lesions or generalized (often serious) when caused by diffuse brain injury. Although rarely seen in domestic animals, one exception to the importance of focal lesions is extracerebral hemorrhage (acute subdural hematoma in human beings), which—though principally involving the surface of one hemisphere—can cause more mass effect (brain swelling) in the underlying cerebral hemisphere than the hematoma itself. In such circumstances (acute subdural hematoma) the small amount of blood in the subarachnoid space is not the sole reason for the patient's neurologic state. If the hematoma is removed, the acute brain swelling can progress so rapidly that the brain protrudes (herniates) through the craniotomy site.

The more serious forms of diffuse brain injury are associated with generalized acute brain swelling. It is sometimes difficult to determine the relative importance of swelling in affected individuals because initial acute swelling (detectable as soon as 30 minutes after injury in human beings) can be followed after several hours to days by true cerebral edema (as a result of increased vascular permeability), which can be

## Pathologic Basis of Veterinary Disease, 4th Edition

the actual deleterious lesion. Peroxidative injury to blood vessels has been one proposed cause of pathologic vasodilation in the posttraumatic CNS.

14.1.1.9.2

### CEREBRAL EDEMA

The basis of our current understanding of cerebral edema was advanced by Klatzo in 1967 when he proposed two distinct types: (1) cytotoxic edema or cell swelling caused by increased intracellular fluid with normal vascular permeability and (2) vasogenic edema or tissue swelling caused by increased extracellular fluid resulting from increased vascular permeability (Fig. 14-29). Other types of cerebral edema have been identified as hydrostatic (or interstitial) edema associated with increased hydrostatic pressure of the CSF (resulting from obstructive internal hydrocephalus) and hypo-osmotic edema, which is dependent on development of an abnormal osmotic gradient between the blood and nervous tissue. The types of edema in the CNS are summarized in Table 14-2. It should be emphasized that, depending on the nature of the injury, multiple mechanisms can contribute to edema in the CNS and these distinctions are not always clearly defined or distinct. For continuity, spongiform change and status spongiosis will also be discussed in this section.

14.1.1.9.2.1

#### Vasogenic Edema

In animals, vasogenic edema is the most common type of edema in the CNS. It occurs following vascular injury often adjacent to inflammatory foci, hematomas, contusions, infarcts, cerebral hypertension, and neoplasms. The underlying mechanism of vasogenic cerebral edema is a breakdown of the blood-brain barrier that results in movement of plasma constituents, such as water, ions, and organic osmolytes, and proteins into the perivascular extracellular space, particularly that of the white matter (Fig. 14-30, A). In addition to extracellular accumulation of fluid, vasogenic edema can also be accompanied by some cellular swelling involving astrocytes. Vasogenic edema with the resulting accumulation of extracellular fluid can cause an increase in intracranial pressure within the CNS. This pressure can also be so severe as to cause neurologic dysfunction and caudal displacement of brain structures, such as the parahippocampal gyri and cerebellar vermis (Figs. 14-86 and 14-87).

14.1.1.9.2.2

#### Cytotoxic Edema

Cytotoxic edema is characterized by the accumulation of fluid intracellularly in neurons, astrocytes, oligodendroglia, and endothelial cells (called hydropic degeneration in other cells of the body) as a result of altered cellular metabolism, often due to ischemia. Although not all of the cells listed previously may be involved in all cases of cytotoxic edema, affected cells swell within seconds of injury. The mechanism is thought to involve an energy deficit that interferes with normal function of the cell's ATP-dependent sodium-potassium pump. Thus the cell cannot maintain homeostasis, which requires the secretion of intracellular sodium, and the elevated concentration of intracellular sodium and presumably other ions as well as organic osmolytes are followed by an increased influx of water. The gray and white matter of the brain are both affected, the brain swells, and the sulci and gyri become indistinct and flattened (Fig. 14-31), respectively. The fluid taken up by the swollen cells is primarily derived from the extracellular space, which becomes reduced in size and has an increased concentration of extracellular solutes.

862

863

**Fig. 14-29 Types of cerebral edema.** **A**, Normal blood-brain barrier. Endothelial cells are red; astrocytes are beige; neurons are light yellow. **B**, Cytotoxic edema. Cytotoxic edema is characterized by the accumulation of fluid intracellularly (in neurons, astrocytes, oligodendroglia, and endothelial cells) as a result of altered cellular metabolism, often caused by ischemia. The gray and white matter are both affected. The fluid taken up by swollen cells is primarily derived from the extracellular space, which becomes reduced in size and has an increased concentration of extracellular solutes. **C**, Vasogenic edema. This type of edema is seen in acute inflammation, and its basic mechanism is an increase in vascular permeability from the breakdown of the blood-brain barrier. This breakdown allows movement of plasma constituents such as water, ions, and plasma proteins into the extracellular space, particularly that of the white matter. (**A**, **B**, and **C**, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois. Based on an illustration from Leech RW, Shuman RM: Neuropathology: a summary for students, Philadelphia, 1982, Harper & Row.)

**Table 14-2 Types of Edema in the Central Nervous System**

Type of Edema	Cause	Outcome
Cytotoxic	Altered cellular metabolism (often due to ischemia)	Intracellular accumulation of fluid (neurons, glial cells, endothelial cells)
Vasogenic	Vascular injury with breakdown of the blood-brain barrier	Extracellular accumulation of fluid (cerebrocortical white matter)
Hydrostatic (interstitial)	Elevated ventricular hydrostatic pressure (hydrocephalus)	Extracellular accumulation of fluid (periventricular white matter)
Hypo-osmotic	Osmotic imbalances (blood plasma vs. extracellular and intracellular microenvironments of the central nervous system)	Extracellular and intracellular accumulation of fluid (cerebrocortical gray and white matter)

## Pathologic Basis of Veterinary Disease, 4th Edition

However, for this lesion to be described accurately as cerebral edema, there must be additional fluid movement into the brain and not merely a change of existing fluid from extracellular to intracellular compartments. In practical terms, this is not always the case and can be difficult to determine. The term *cytotoxic edema* has been used rather loosely to refer simply to cellular swelling in many cases.

863

864

Additional fluid may originate from the circulation by way of the transcapillary fluid exchange or possibly from the CSF, which has extensive diffusional communication with the extracellular fluid of the brain. The blood-brain barrier remains intact during development of this type of edema, so fluid does not enter the brain by a disturbance in vascular permeability. Specific causes of this lesion include hypoxia-ischemia, particularly in the early stages; intoxication with metabolic inhibitors, such as 2,4, dinitrophenol, 6-aminocaproic acid, and ouabain; and severe hypothermia.

**Fig. 14-30 Edema. A, Vasogenic edema.** The perivascular spaces are wide as a result of fluid leakage through the blood-brain barrier (*arrows*) (*Fig. 14-29*). A similar change can be seen around neurons. These fluid-filled spaces are often very difficult to differentiate from artifactual spaces caused by shrinkage from fixation and dehydration in the preparation of the paraffin-embedded sections. H&E stain. **B, Edema (spongy change, status spongiosis), hepatic encephalopathy, dog.** This lesion is characterized by variably sized fluid-filled spaces within the white matter (*arrows*). It can develop by several different mechanisms, which include splitting of myelin sheaths, accumulation of extracellular fluid, and swelling of astrocytic and neuronal cellular processes. Such changes can reflect osmotic imbalances as well as a direct toxic effect on cells (cytotoxic edema). H&E stain. (*A and B, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.*)

14.1.1.9.2.3

### Interstitial (Hydrostatic) Edema

Interstitial edema is characterized by the accumulation of fluid in the extracellular space of the brain because of elevated ventricular hydrostatic pressure that accompanies hydrocephalus. Fluid moves

## Pathologic Basis of Veterinary Disease, 4th Edition

---

across the ependyma of the ventricular wall and accumulates extracellularly in the periventricular white matter. Unlike the other forms of cerebral edema that cause swelling of affected CNS tissue, hydrostatic edema causes variable degeneration and loss of the periventricular white matter mostly through primary demyelination accompanied by loss of axons. As the periventricular white matter is reduced in volume, the ventricle expands to fill the void by displacement, thereby exacerbating the hydrocephalus. The blood-brain barrier remains intact in hydrostatic edema.

14.1.1.9.2.4

### Hypo-Osmotic Edema

Hypo-osmotic edema occurs following overconsumption of water (water intoxication) leading to dilution of the osmolality of the plasma. Under normal conditions the osmolality of CSF and extracellular fluid in the CNS is slightly greater than that of plasma. When the osmolality of plasma is further decreased, water moves from the vasculature into the brain following the osmotic gradient resulting in osmotic edema. This form of edema accounts for the clinical signs and lesions in osmotic demyelination syndrome and salt poisoning, as discussed later.

14.1.1.9.3

### SPONGIFORM CHANGE AND STATUS SPONGIOSUS

Spongiform change is a phrase whose exact meaning varies in different scientific disciplines and experimental situations. In this chapter, wherever possible, spongiform change will be used to describe morphologic changes in H&E stained sections that occur primarily in gray matter. These changes are characterized by small clear vacuoles of varied sizes that form in the cytoplasm of neuron cell bodies and proximal dendrites in diseases such as the transmissible spongiform encephalopathies (TSEs) and rabies encephalitis and in the processes of astrocytes that are spatially related to the affected neurons.

Status spongiosus (spongy degeneration) is also a phrase whose exact meaning varies. It is defined as multiple fluid-filled clear spaces in the white matter of H&E stained sections of the CNS and may be extracellular or intracellular (Fig. 14-30, B). This lesion results from the accumulation of edema fluid in the white matter secondary to a variety of causes, including cytotoxic edema, vasogenic edema, intramyelinic edema, Wallerian degeneration, and other hypoxic, toxic, and metabolic diseases.

864

865

**Fig. 14-31 Cerebral edema, polioencephalomalacia, sheep.** On the dorsal surface, gyri are swollen and flattened and sulci have become less distinct. Accumulation of extracellular fluid has caused the brain to swell, and because space within the cranial vault is limited, the brain has been pressed against the calvarium. In extreme cases, notable brain swelling can cause caudal displacement of the vermis of the cerebellum and the parahippocampal gyri (Figs. 14-86 and 14-87). Faint yellow discoloration indicates areas of necrosis. (Courtesy College of Veterinary Medicine, University of Illinois.)

In some instances the term *spongy degeneration* or *spongy change* has been used in the veterinary literature to describe microscopic lesions in a group of diseases of young dogs, cats, and cows characterized by fluid accumulation in white matter. These diseases will be discussed in later sections.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 14.1.1.10 BARRIER SYSTEMS OF THE CENTRAL NERVOUS SYSTEM

The CNS has several unique structural and functional barrier systems that serve to protect it from diseases affecting the vascular and ventricular systems and to actively facilitate transfer of necessary molecules, such as glucose, to cells within the CNS.

#### 14.1.1.10.1 BLOOD-BRAIN BARRIER

The blood-brain barrier, formed by vascular endothelial cells, endothelial-derived basement membrane, and foot processes of astrocytes, exists in the capillaries of the CNS (Fig. 14-16). The most important structural component of the blood-brain barrier is the tight junctions between endothelial cells of cerebral capillaries. By means of the blood-brain barrier, the CNS can selectively regulate its extracellular compartment and isolate itself from sudden biochemical changes that may occur in the systemic circulation. In the majority of the CNS, endothelial cells are nonfenestrated and are held together by intercellular tight junctions. These tight junctions actively prevent the movement of protein, hydrophilic molecules, and ions from capillary lumina into the intercellular compartment of the CNS. Endothelial cells also have a transmembrane lipophilic pathway for the diffusion of small lipid molecules and numerous highly selective polarized receptor-mediated transport systems for molecules such as insulin, transferrin, glucose, purines, and amino acids. Finally, endothelial cells express a net negative charge on their abluminal side and at the basement membrane, providing an additional selective mechanism that impedes movement of anionic molecules such as chloride ions across the barrier. Foot processes of astrocytes cover more than 90% percent of the abluminal surface of capillary endothelial cells. Experimental evidence suggests that secretion of growth factors from astrocytes promotes the formation and maintenance of the blood-brain barrier.

Capillaries in the area postrema, median eminence, neurohypophysis, pineal body, subfornical organ, commissural organ, and supraoptic crest lack tight junctions and are fenestrated; thus the blood-brain barrier is absent at these sites.

#### 14.1.1.10.1.1 Glia Limitans

The CNS is separated from the subarachnoid CSF by the pia mater and the glia limitans (Fig. 14-16). The glia limitans, which covers the outer surface of the brain and spinal cord and is situated immediately subjacent to the pia mater, consists of astrocytic fibers with many foot processes that form a distinct layer that lies subjacent to the pia mater. In many areas the pia is only one-cell-layer thick and has fenestrations, so that the glia limitans is exposed directly to the subarachnoid space. As arterioles penetrate the cerebral cortex to supply the CNS with blood, they carry the pia mater and surrounding glia limitans with them until the arteriole structurally and functionally becomes a capillary. At the capillary level, the pia mater disappears but the layer of pericapillary astrocytic foot processes remains and serves as a component of the blood-brain barrier. This transition zone occurs at a depth approximately 1 to 3 mm within the cerebral cortex.

865

866

#### 14.1.1.10.2 BLOOD-CEREBROSPINAL FLUID BARRIER

The blood-CSF barrier is formed by the choroid plexus and the arachnoid. This barrier is formed by tight junctions between apposing surfaces of choroid plexus epithelial cells that cover the choroid plexuses. As

## Pathologic Basis of Veterinary Disease, 4th Edition

---

noted previously, blood vessels of the choroid plexus are fenestrated. The barrier formed by tight junctions between choroid plexus epithelial cells restricts the movement of molecules that leak from fenestrated capillaries into the extracellular compartment of the choroid plexus and then into the CSF. Similarly, the arachnoid membrane also has tight junctions that prevent the movement of molecules from the blood into the CSF. The arachnoid membrane is generally impermeable to hydrophilic molecules but lacks specialized transport systems, and its role in forming the blood-CSF barrier is largely passive.

### 14.1.1.10.3 CEREBROSPINAL FLUID–BRAIN BARRIER (EPENDYMAL BARRIER)

The CNS is separated from ventricular CSF by ependymal epithelial cells and foot processes of astrocytes. Although the ependymal lining does form a cellular barrier of sorts, materials within the ventricular system can without too much difficulty penetrate into the brain. The CSF-brain barrier is far more permeable than the blood-brain barrier.

### 14.1.1.11 DEFENSE MECHANISMS OF THE CENTRAL NERVOUS SYSTEM

Although infectious agents have developed unique approaches to gain entry into the CNS, the body has also evolved a strong suite of defense mechanisms to protect the CNS against infectious pathogens and disease processes. The skin and mucous membranes of the alimentary, respiratory, and urinary systems provide structural and functional barriers against disease. The inflammatory response, immune system, and monocyte-macrophage system provide a strong local and systemic defense against pathogen replication and disease spread. Finally, barrier systems in the CNS, reviewed in an earlier section, represent structural and functional protection against a wide range of pathogens and toxic injuries. These defense mechanisms are summarized in [Box 14-5](#).

#### 14.1.1.11.1 INFLAMMATION OF THE CENTRAL NERVOUS SYSTEM

Inflammation of the CNS is different from inflammation in other organs because of the presence of the blood-brain barrier. Under normal conditions, this barrier provides limited isolation of the CNS from circulating cellular and humoral elements of the immune system. Macrophages (monocytes) and T lymphocytes can penetrate an intact blood-brain barrier and enter the perivascular and subarachnoid spaces, transit these spaces, and return to the circulation in a role of protective immunologic surveillance of the CNS.

## Pathologic Basis of Veterinary Disease, 4th Edition

14.1.1.11.1.1.3	<b>MENINGES, CEREBROSPINAL FLUID</b>  Structural and functional (continuous flow of cerebro-spinal fluid [CSF]) barrier
14.1.1.11.1.1.4	<b>BARRIER SYSTEMS</b>
14.1.1.11.1.1.4.1	<b>Blood-brain barrier</b>  Structural and functional barrier formed by vascular endothelium, basement membrane, and astrocytic foot processes. This barrier regulates the movement of agents from the blood to the central nervous system (CNS).
14.1.1.11.1.1.4.2	<b>Blood-CSF barrier</b>  Structural and functional barrier formed by choroid plexuses cells and the arachnoid membrane. This barrier regulates movement of agents from the blood to the CSF.
14.1.1.11.1.1.5	<b>GLIA LIMITANS</b>  Formed by astrocytic foot processes immediately subjacent to the pia mater. This structure may have some barrier function in preventing movement of microbes from CSF into the CNS through the pia mater.
14.1.1.11.1.1.6	<b>MICROGLIA, TRAFFICKING MACROPHAGES</b>  Resident and migrating cells that are part of the monocyte-macrophage system.
14.1.1.11.1.1.7	<b>IMMUNOLOGIC RESPONSES</b>  Innate and adaptive immunologic responses that form the body's overall immune system.

It is important to remember that inflammation in the CNS is regulated by a complex system of recognition and adhesion molecules, cytokines, chemokines, and their corresponding receptors (review [Chapters 3 and 4](#)). In particular within the CNS, chemokines and their receptors regulate physiologic and pathologic leukocyte trafficking and cellular migration events.

866

867

When pathogens use one of the four portals of entry to gain access to the CNS, the inflammatory process that ensues disrupts the blood-brain barrier. Thus in addition to inflammation, edema and hemorrhage can result. Selectins and integrins in cooperation with chemokines are active in initiating and regulating the acute inflammatory response and the movement of neutrophils across the blood-brain barrier in response to a variety of pathogens. Migration of inflammatory cells within the CNS is poorly understood. Chemotactic gradients are likely established by chemokines that diffuse from sites of production within foci of inflammation. Activated glial cells, including astrocytes and resident microglia, form chemokine networks in areas of inflammation in response to cytokines produced by T lymphocytes that recognize foreign antigens.

Depending on the type of antigen and the pathogenicity of the infectious agent, the inflammatory response will resolve (heal) or progress to a chronic or granulomatous phase with attempts at resolution and

## Pathologic Basis of Veterinary Disease, 4th Edition

clearance of the infectious agent. In the CNS, the type of inflammatory response can vary with the cause. A rather simplistic guideline, to which there are always exceptions, that compares the type of inflammation with different causal agents is as follows:

1. Serous to suppurative or purulent responses can be due to several species of bacteria.
2. Eosinophil responses occur in salt poisoning of pigs and with parasitic larval migration.
3. Lymphocytic, monocytic/macrophage, nonsuppurative, lymphomonocytic, and lymphohistiocytic responses can be due to viruses and certain protozoa.
4. Granulomatous response can be due to fungi, certain protozoa, and some higher-order bacteria, such as the *Mycobacterium* spp.

### 14.1.1.12 PORTALS OF ENTRY INTO THE CENTRAL NERVOUS SYSTEM

Disease processes of the CNS enter the brain and spinal cord through one of four principal portals (Box 14-6). These portals include: (1) direct extension, (2) hematogenous entry, (3) leukocytic trafficking, and (4) retrograde axonal transport.

#### 14.1.1.12.1 DIRECT EXTENSION

Direct extension is a common portal of entry and includes a wide range of disease processes. Penetrating trauma through the calvarium or vertebrae as a result of a gunshot wound or other forms of trauma can provide a direct portal into the CNS. Disease processes can also extend into the brain and/or spinal cord as a result of: (1) a middle and/or inner ear infection (Fig. 14-32), (2) nasal cavity/sinus infection or neoplasia through the cribriform plate or calvarium (Fig. 14-33), or (3) bacterial osteomyelitis or neoplasia of vertebral bodies with extension through the vertebrae into the vertebral canal.

14.1.1.12.1.1.4

### RETROGRADE AXONAL TRANSPORT

Transported from the periphery into the CNS by neuronal retrograde axoplasmic flow

**Fig. 14-32 Chronic bacterial abscess, leptomeninges of the cerebellum, sheep.** The abscess (*arrow*) resulted from direct extension of infection from an inner ear infection and compresses and distorts the cerebellum. It is walled off from the adjacent cerebellum by a distinct fibrous capsule synthesized by fibroblasts from the adjacent leptomeninges. This abscess likely arose in the leptomeninges of the cerebellum and grew to compress adjacent cerebellum. (*Courtesy College of Veterinary Medicine, University of Illinois.*)

Benign growths of the calvarium and vertebrae, such as osteomas, chondromas, and osteochondromas, often extend into and compress the brain and spinal cord. One specific neoplasm, the multilobular osteoma, has been described as originating from the periosteum of the canine skull. Also, malignant neoplasms adjacent to the cranium or spinal column can cause injury by direct invasion. Some examples include extracranial osteosarcoma and fibrosarcoma in the dog. Also, malignant melanoma of the soft palate in the dog and melanoma involving the paravertebral lymph nodes in the horse can invade adjacent CNS tissue. Other examples of direct extension include lymphosarcoma affecting the spinal cord in the bovine species and less frequently involving the spinal cord or brain in the dog and cat and carcinomas of the ethmoidal area and nasal cavity.

Fig. 14-33 **Osteochondrosarcoma, calvarium, dog.** The neoplasm has destroyed and penetrated the calvarium and compressed the cerebral hemispheres (*arrows*). There is also invasion of frontal or nasal sinuses and nasal cavity. (Courtesy Dr. K. Bailey, College of Veterinary Medicine, University of Illinois.)

### 14.1.1.12.2 HEMATOGENOUS ENTRY

The most common portal of entry into the CNS is the blood stream. In neonates, infectious agents such as *Escherichia coli* can enter the blood through the umbilical vein or through the venous system following surgical procedures, such as castration. A CNS disease in cows called thrombotic meningoencephalitis is caused by *Histophilus somni* (formerly *Haemophilus somnus*) bacteremia with localization of bacteria in blood vessels of the brain, which leads to vasculitis, hemorrhage, and thrombosis (Fig. 14-27). In adult animals, sites of chronic inflammation, such as abscesses, bacterial skin disease, and ear infections, can also serve as sustained sources of bacteria, which can enter the venous system and spread to distant sites through the blood stream hematogenously.

Capillary beds of the meninges, neuropil, and choroid plexuses are common sites for localization of specific infectious agents. Such localization patterns may be attributable to receptor-mediated phenomena or vascular flow patterns related to the size of the infectious pathogen. Additionally the blood stream is also a portal of entry into the CNS for metastasizing tumors, such as hemangiosarcoma and a variety of carcinomas.

### 14.1.1.12.3 LEUKOCYTIC TRAFFICKING

As part of the systemic immunologic surveillance system, macrophages (monocytes) and lymphoid cells continually move in and out of capillary beds in the CNS and thus serve as sentinel cells monitoring for

## Pathologic Basis of Veterinary Disease, 4th Edition

---

the presence of disease processes within the brain and spinal cord. As examples, retroviruses, such as feline leukemia virus, and mycotic agents, such as *Blastomyces dermatitidis*, have stages of their life cycles within the cytoplasm of lymphocytes or macrophages. During the movement of lymphocytes and macrophages in and out of the CNS, cells infected with such agents are activated to release their infectious contents and infect cells of the CNS.

### 14.1.1.12.4 RETROGRADE AXONAL TRANSPORT

Retrograde axonal transport provides a unique portal of entry for viruses such as rabies and the bacterium *Listeria monocytogenes*. These pathogens replicate in tissues richly innervated with receptors and motor end plates from sensory and motor neurons, respectively, which provide a connection between peripheral infection and the CNS. Retrograde axoplasmic flow is then used to gain entry into the CNS (Fig. 14-6).

### 14.1.2 DISEASES

#### 14.1.2.1 MALFORMATIONS

##### 14.1.2.1.1 NEURAL TUBE CLOSURE DEFECTS (DYSRAPHIA)

*Dysraphia* literally means an abnormal seam, and these anomalies appear to result from defective interaction of neuroepithelium with adjacent notochordal and mesenchymal cells during closure of the neural tube in the early stages of development. Neuroepithelium is the progenitor cell for neurons and astrocytes, oligodendrocytes, and ependymal cells.

Experimental studies of closure of the neural tube show that it occurs at four distinct locations called closure initiation sites in the embryo, and disruption of this process at these sites leads to site-specific dysraphic anomalies. Closure site I contributes to the posterior neuropore (the opening at the posterior end of the embryonic neural canal), whereas closure sites II to IV contribute to the anterior neuropore (the opening at the anterior end of the embryonic neural canal). Anencephaly is caused by a failure of closure sites II or IV; spina bifida is caused by a failure of closure site I. Genes possibly involved in neural tube closure defects include those of the folate metabolic pathway and folate transport.

868

869

Dysraphic anomalies, also called neural tube closure defects, in animals are typified by anencephaly and prosencephalic hypoplasia, cranium bifidum, and spina bifida.

##### 14.1.2.1.1.1 Anencephaly and Prosencephalic Hypoplasia

*Anencephaly* literally means an absence of the brain, but in many instances of so-called anencephaly only the rostral part of the brain (cerebral hemispheres) is absent, or very rudimentary, and to varying degrees the brain stem is preserved. Thus this abnormality is best-designated prosencephalic hypoplasia. Such anomalies result from an abnormal development of the rostral aspect of the neural tube. Although the cause for these anomalies is largely unknown, anencephaly has been reported to be associated with anomalies in other body systems in calves. Additionally, anencephaly—following initial cranium bifidum and exencephaly (protrusion of brain not covered by skin or meninges)—has been reported to occur in rat fetuses after exposure of the pregnant dam to excessive concentrations of vitamin A and cyclophosphamide.

## Pathologic Basis of Veterinary Disease, 4th Edition

14.1.2.1.1.2

### Meningoencephalocele and Cranium Bifidum

Cranium bifidum is characterized by a dorsal midline cranial defect through which meningeal and brain tissue can protrude. The protruded material, which forms a sac (-cele), is covered by skin and can be lined by meninges (meningocele) or meninges accompanied by a part of the brain (meningoencephalocele) (Fig. 14-34). These malformations are hereditary in pigs and cats and are also caused by griseofulvin treatment in pregnant cats during the first week of gestation.

14.1.2.1.1.3

### Meningomyelocele and Spina Bifida

Spina bifida is the vertebral counterpart of cranium bifidum. This lesion, which frequently tends to affect the caudal spine, is characterized by a dorsal defect in the closure of one to several vertebral arches that form the dorsal spinal column covering the spinal cord. The lesion results from a failure of the neural tube and developing vertebral arches to close properly, which may result in herniation of either meninges (meningocele) or meninges and spinal cord (meningomyelocele) through the defect, forming a sac covered with skin. In some cases there is no herniation of the meninges or spinal cord through the defect, and this variation is termed spina bifida occulta (Fig. 14-35). In this variation, there is an absence of skin over the affected vertebral arches, vertebral musculature is visible, and the dura mater and spinal cord can be seen in the spinal canal.

Spina bifida has been reported in several species, including horses, calves, sheep, dogs (especially English bulldogs), and cats, particularly the Manx breed, in which it is inherited as an autosomal dominant trait. An additional lesion, myeloschisis, is similar to spina bifida except in its severe form it results from failure of the entire spinal neural tube to close. This lesion is therefore characterized by lack of development of the entire dorsal vertebral column.

869

870

**Fig. 14-34 Meningocele (M), brain, calf.** A defect in the caudodorsal portion of the skull has allowed the meninges to herniate into a large external pouch covered by skin. The pouch contains fluid and is lined by arachnoid and dura, which are continuous with those surrounding the brain. The cerebellum is small and the occipital cortex truncated. Scale bar = 5 cm. (Courtesy Dr. R. Storts, College of Veterinary Medicine, Texas A&M University.)

**Fig. 14-35 Spina bifida occulta, calf.** There is a cleft in several vertebrae of the dorsal spinal column resulting from defective closure of the neural tube. Although not always the case, note the lack of herniation of the meninges or spinal cord through the defect. The spinal cord is not visible (i.e., occulta) because it is located in the vertebral canal at the deepest ventral extent of the cleft and is covered by edematous muscle. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

14.1.2.1.1.4

### Hydromyelia

Congenital hydromyelia is an abnormal dilatation of the central canal of the spinal cord (Fig. 14-36) that leads to the formation of a cavity in which CSF may accumulate. In animals, this disorder likely results from infectious or genetic injury that results in damage to ependymal cells lining the canal and the subsequent disruption of the normal flow of CSF and the formation of abnormal CSF pressure gradients within the central canal. As CSF accumulates in the enlarging space, the increased pericanalicular pressure placed on the spinal cord compresses the white and gray matter, leading to loss of white matter and possibly neurons in gray matter. Acquired hydromyelia is rare and is caused by

## Pathologic Basis of Veterinary Disease, 4th Edition

obstruction of the central canal CSF flow. Causes of obstruction include infection, inflammation, and neoplasia.

Clinical signs in young animals with congenital hydromyelia vary depending on the location and size of the dilatation of the central canal in the spinal cord. Signs may include ataxia, urinary incontinence, respiratory difficulty, muscle weakness in front and/or hind limbs, and abnormal proprioceptive reflexes.

**Fig. 14-36 End-stage hydromyelia, spinal cord, dog.** The white and gray matter of the spinal cord are missing as a result of compression atrophy from a space-occupying, fluid-filled central canal. The only recognizable remnants of nervous tissue is the dura (*arrows*). In less severely affected animals, there would be variable dilatation of the central canal of the spinal cord with much less severe compression atrophy. (*Courtesy College of Veterinary Medicine, University of Tennessee.*)

### 14.1.2.1.2 NEURONAL MIGRATION DISORDERS

#### 14.1.2.1.2.1 Lissencephaly

Lissencephaly (agyria) and a similar change called pachygyria (large gyria) are developmental anomalies that result in a part or the entire cerebrum having smooth surfaces lacking normal gyri and

## Pathologic Basis of Veterinary Disease, 4th Edition

sulci (Fig. 14-37). The cortex is thicker than normal on a transverse section, and the normal laminar pattern of neurons is disrupted.

This lesion is thought to have a genetic basis and results from an arrest of or defect in neuronal migration during development. Recent experimental studies suggest that this migrational disorder is linked to mutations and/or deletions in the doublecortin, filamin-1, LIS1, and reelin genes. These genes control the spatial and temporal expression of proteins in the extracellular microenvironment that subsequently bind to receptors on migrating cells. Patterns of cell membrane binding signals are interpreted by migrating cells and are reflected in their movements by changes in intracellular cytoskeletal reorganization. This process allows cells to migrate to their final destinations within the CNS. Thus alterations in signaling pathways lead to abnormal neuronal migration and CNS anomalies.

The brains of some laboratory animals, such as rabbits, rats, and mice, lack gyri and sulci; therefore agyria is normal in these species and has no functional significance.

**Fig. 14-37 Lissencephaly, brain, dog.** Note the smooth surfaces of the cerebral hemispheres, which are without gyri and sulci. Gyri and sulci fail to form, possibly from failure of neuronal development and migration. Lissencephaly is an abnormality in domestic animals, but is normal in mice, rats, rabbits, and birds. (Courtesy Dr. L. Roth, College of Veterinary Medicine, Cornell University.)

870

### 14.1.2.1.3 ENCEPHALOCLASTIC DEFECTS

871

#### 14.1.2.1.3.1 Porencephaly and Hydranencephaly

The formation of fluid-filled cavities in the brain, termed porencephaly (small cavities) and hydranencephaly (large cavities), usually occurs in utero during gestation. *Porencephaly* refers to a

## Pathologic Basis of Veterinary Disease, 4th Edition

cleft or cyst in the wall of the cerebral hemisphere that typically communicates with the subarachnoid space, but it can also communicate with a lateral ventricle. The cavitation results from destruction of immature neuroblasts whose loss prevents normal development as a result of faulty or aberrant neuroblast migration. Hydranencephaly is considered a severe form of porencephaly and is characterized by cavitation in areas normally occupied by the white matter of the cerebral hemispheres and results from improper development of this part of the cerebrum. Hydranencephaly is often quite severe, with very little tissue present between the dilated lateral ventricles and the leptomeninges.

Type I and type II porencephaly have been described in human infants, and cases of porencephaly reported in animals can also be categorized using this scheme. Type I porencephaly is caused by vascular injury or vasculitis. Injury, resulting in infarction in the area of the subependymal germinal matrix, results in the formation of a cyst within the focus of dead cells and effete erythrocytes. The germinal matrix is very sensitive to ischemia because of sparse stroma, delicate vasculature, and high metabolism. The initial focus of hemorrhage can grow by centripetal expansion, depending on the severity of hemorrhage and hypoxia, into a cyst of considerable size. Type II porencephaly is caused by injury of neuroblasts in the germinal matrix and the failure of these neuroblasts to migrate within the matrix to form the cerebral cortex. A cyst results from the expansion of the subarachnoid space into the void left by the absence of the cortex.

Type II porencephaly appears to be the form of porencephaly that occurs in domestic animals. Viruses, such as those that cause Akabane disease, bovine virus diarrhea, blue tongue, border disease, Rift Valley fever, and Wesselsbron disease infect and destroy differentiating neuroblasts and neuroglial cells in the developing fetus in utero. Although neuroblasts appear to be the primary target for viral infection in these diseases, additional experimental studies need to be conducted to clarify whether endothelial cells are also infected.

Grossly, porencephaly/hydranencephaly appears as thin-walled fluid-filled cysts of varied sizes in the cerebral hemispheres. Because of the lack of brain substance, the ventricles expand into this space (hydrocephalus ex vacuo), and the ependymal lining remains relatively preserved or may have scattered defects characterized by absent ependyma. The cranium and meninges are generally unaltered. In some cases, cerebellar hypoplasia (all or part of the cerebellum) and hypoplasia of the spinal cord may also occur. Microscopically, necrosis of undifferentiated cells, including potential neuroblasts and neuroglia, surrounding a fluid-filled cavity is present in the subventricular zone of the cerebral hemispheres. Degeneration and loss of motor neurons of the ventral horns of the spinal cord may also be observed. This lesion may result in denervation atrophy of limb muscles with a resultant lack of joint movement and arthrogryposis, a persistent congenital flexure or contraction of a joint. Nonsuppurative encephalitis, typified by the accumulation of macrophages, lymphocytes, and plasma cells, also occurs.

### 14.1.2.1.4 MALFORMATIONS OF THE CEREBELLUM

#### 14.1.2.1.4.1 Cerebellar Hypoplasia

In animals the most common causes of cerebellar hypoplasia are parvoviruses (kittens [panleukopenia virus {Fig. 14-38}], puppies [canine parvovirus]), and pestiviruses (calves [bovine virus diarrhea virus {Fig. 14-39}], piglets [classical swine fever virus]). These viruses infect and destroy mitotic cells, primarily the cells of the external granular layer of the cerebellum that are still dividing during the late gestational and early neonatal periods. Necrosis of these cells means they are not available to migrate

871

872

## Pathologic Basis of Veterinary Disease, 4th Edition

to form the internal granular layer, and thus the cerebellum is hypoplastic. In calves the cerebellar lesion (cerebellar hypoplasia/atrophy), which follows infection at 150 days of gestation (mid trimester), is considered to involve two processes. One process is typified by early necrosis of the undifferentiated cells in the external granular layer. A second process involves viral-induced vasculitis and ischemia of cerebellar folial white matter.

**Fig. 14-38 Cerebellar hypoplasia, brain, cat.** In the cat, cerebellar hypoplasia (cerebellar hypoplasia, top specimen; normal cat, bottom specimen) most commonly is the result of in utero infection with feline panleukopenia virus (parvovirus). The virus infects and causes lysis of dividing cells in the external granular layer (on the outside of the cerebellum in the fetus). Because these cells are no longer available to migrate to form the (internal) granular layer, the cerebellum remains small.  
(Courtesy Dr. Y. Niyo, College of Veterinary Medicine, Iowa State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Fig. 14-39 **Cerebellum, calf.** **A**, Cerebellar hypoplasia (*arrow*). In utero infection with bovine viral diarrhea virus (pestivirus) results in cytolysis of dividing germinal cells of the external granular layer ([Fig. 14-39, B](#)) and vascular impairment secondary to vasculitis of the cerebellum during organogenesis. The severity of the lesion involving the granule cells is at its greatest if dividing cells are infected during the earliest stages of cellular differentiation, and occurs between 100 to 180 days of gestation. **B**, Normal neonatal calf, external granular layer of the cerebellum (*arrow*). Although many of these cells migrate to form the (internal) granular layer, some are still present at the time of birth in many domestic animals. Bovine viral diarrhea virus infects and kills mitotic cells of the external granular layer of the cerebellum. These cells are still dividing during the late gestational and early neonatal periods in the cat and between 100 to 180 days of gestation in the calf. Necrosis of these cells means they are not available to migrate to form the internal granular layer, and thus the cerebellum does not obtain full size. Depending on the stage of gestation, injury can also alter development of cells in others ways including altered patterns of migration, resulting in various other lesions termed dysplasia. H&E stain. (**A and B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Grossly the size of the cerebellum is reduced; the reduction in size varies in severity depending on the age and developmental stage of the brain when the fetus or neonate is infected.

Microscopically there is necrosis and loss of the external granular layer and degeneration and loss of Purkinje cells that are postmitotic but immature. Reasons for degeneration of Purkinje cells might include infection by the virus or lack of normal development of the cerebellar cortex. The Purkinje cells can also be malpositioned and located in the molecular layer as a result of the viral-induced alteration in development of the cerebellar cortex. In calves, edema of the folial white matter with focal hemorrhage in the cortex, followed by focal cavitation of the white matter and atrophy, may also be

## Pathologic Basis of Veterinary Disease, 4th Edition

---

present. These latter lesions are due to ischemia resulting from vasculitis. Leptomeningitis, characterized by accumulation of lymphocytes and plasma cells and occasionally fibroplasia, may cause adhesions between adjacent cerebellar folia and focal obliteration of the subarachnoid space.

### 14.1.2.1.5 MALFORMATIONS OF THE SPINAL CORD

#### 14.1.2.1.5.1 Syringomyelia

Syringomyelia (congenital and acquired forms) is a disorder in which a cyst forms in the spinal cord. The cyst, a tubular cavitation called a syrinx, is not lined by ependyma and is separate from the central canal. The syrinx can extend over several spinal cord segments. The lesion is well known in human beings and has also been described in the dog (Weimaraner breed) and calves. The syrinx can communicate with the central canal but should not be confused with hydromyelia, which means dilatation of the central canal. The cavity contains fluid and is unlined, except for varying degrees of mural astrocytosis, which is usually very mild in the Weimaraner. Proposed causes include presence of an anomalous vascular pattern that results in low-grade ischemia, leading to infarction or failure of cells destined for this area to develop in utero trauma in human beings or an infection that causes degeneration and cavitation. A rare acquired form of syringomyelia is similar to congenital syringomyelia; however, it occurs in older animals. Proposed causes include injury following trauma to the central canal or its vascular supply caused by trauma, infection, or neoplasia that result in degeneration and cavitation of the spinal cord.

872

873

Although the central canal of the spinal cord is connected to the ventricular system via the fourth ventricle, there apparently is little active movement of CSF within the central canal. Recently it has been hypothesized that there may be alteration of “normal” CSF flow (see Ependyma, under Cells of the Central Nervous System) with redirection of the flow along a pressure gradient into the central canal and into the syrinx. It has also been suggested that pressure differences in the vertebral column cause CSF to continually move into the cyst, resulting in enlargement of the syrinx and additional compressive damage to the spinal cord.

Clinical signs in young dogs and calves with syringomyelia vary depending on the location and size of the cyst in the spinal cord. Signs may include ataxia, urinary incontinence, respiratory difficulty, muscle weakness in front and/or hind limbs, and abnormal proprioceptive reflexes.

### 14.1.2.1.6 HYDROCEPHALUS

The most common congenital malformations and developmental anomalies in veterinary medicine affecting cells that form the ependyma and choroid plexuses are hydrocephalus, hydromyelia, and syringomyelia. These anomalies will be covered in greater detail later. Of these anomalies, hydrocephalus is the anomaly most likely to be caused by in utero injury following viral infection of the developing fetus. However, in some breeds (brachycephalic breeds), these disorders may have a genetic predisposition, but this mechanism of injury has not been as clearly established in domestic animals as it has in human beings.

In laboratory animals, several neonatal in utero viral infections, including mumps virus, reovirus type I, and parainfluenza virus types I and II, can induce congenital hydrocephalus. Parainfluenza virus can also cause the lesion in the dog. Although there are some differences among the different viral infections, the basic lesion is stenosis of the mesencephalic duct (aqueduct of Sylvius in human beings, mesencephalic aqueduct) that results in the development of noncommunicating hydrocephalus. In the dog, closure of the

## Pathologic Basis of Veterinary Disease, 4th Edition

---

mesencephalic duct can be incomplete. The virus grows in and causes destruction of ependymal cells lining the ventricular system. The infection is initially accompanied by an inflammation that resolves within 2 weeks.

The notable lesion resulting from this injury to the ependyma of the mesencephalic duct is its occlusion. This end-stage lesion is not the result of an astroglial response or due to the presence of viral antigen. Instead, the original ependyma-lined aqueduct is replaced by focal aggregates of remaining ependymal cells that have separated from the adjacent tissue, which appears normal. The appearance of the final lesion is therefore more suggestive of an agenesis than a viral infection. Infection of adult laboratory animals (mice with influenza viral infection) also can induce mesencephalic duct stenosis resulting in hydrocephalus, but in contrast to neonatal infection, there is a persistent astroglial response in the area of stenosis.

14.1.2.1.6.1

### Congenital Hydrocephalus

CSF can accumulate in the ventricular system, the subarachnoid space, or both. The type of hydrocephalus that develops depends on the site of blockage that disrupts normal flow of CSF.

Exactly which portions of the ventricular system will be dilated in hydrocephalus depends on the site of the blockage:

1. Blockage of the interventricular foramen between a lateral and third ventricle leads to unilateral dilatation of that lateral ventricle.
2. Blockage of both interventricular foramina leads to bilateral dilatation of both lateral ventricles.
3. Blockage of the mesencephalic duct leads to bilateral dilatation of both lateral ventricles, the third ventricle, and the segment of the mesencephalic duct proximal to the blockage.
4. Blockage of the lateral apertures of the fourth ventricle leads to bilateral dilatation of lateral ventricles, the third ventricle, the mesencephalic duct, and the fourth ventricle.
5. Blockage of reabsorption leads to bilateral dilatation of lateral ventricles, the third ventricle, the mesencephalic duct, the fourth ventricle, and the subarachnoid space.

As an example, following blockage of the interventricular foramina, the pressure in the lateral ventricles increases; the ventricles dilate; the ependyma becomes atrophied and focally discontinuous; and because of the pressure gradient, CSF is forced into the periventricular white matter leading to hydrostatic edema. Hydrostatic edema results in degeneration and atrophy of myelin and axons, and this loss of tissue results in further expansion of the ventricles.

The forms of hydrocephalus are communicating and noncommunicating hydrocephalus. Communicating hydrocephalus, the least common of the two forms, occurs when there is communication of ventricular CSF with the subarachnoid space where the CSF can be in excess. Noncommunicating hydrocephalus results from obstruction within the ventricular system at, or rostral to, the lateral apertures of the fourth ventricle. An area of great vulnerability for obstruction is the mesencephalic aqueduct. Noncommunicating hydrocephalus can also occur without any evidence of obstruction to CSF flow as a result of failure of the reabsorption of CSF.

873

874

## Pathologic Basis of Veterinary Disease, 4th Edition

---

A recent hypothesis proposes that communicating hydrocephalus is caused by a decreased expansion of intracranial arteries during systole as a result of reduced compliance involving the arterial walls, or the subarachnoid space, and is referred to as “restricted arterial pulsation hydrocephalus.” Because the intracranial arteries cannot fully expand, a pressure gradient develops in which there is greater pressure within the brain tissue and the ventricles than outside the brain. Several causes have been advanced, including arteritis, subarachnoid hemorrhage, and meningitis.

A third type of hydrocephalus, referred to as hydrocephalus ex vacuo (or compensating hydrocephalus), is not usually a congenital abnormality but occurs secondary to absence or loss of cerebral tissue. This type of hydrocephalus can occur in utero from destruction and loss of cerebral tissue surrounding the lateral ventricles (e.g., in hydranencephaly). Hydrocephalus ex vacuo is discussed further under Acquired Hydrocephalus.

In domestic animals, congenital hydrocephalus can be caused by in utero viral infections leading to aqueductal stenosis (incomplete closure) in the dog that results in the development of noncommunicating hydrocephalus; however, a genetically programmed predisposition may occur in very small and brachycephalic breeds of dogs.

Gross lesions associated with communicating and noncommunicating congenital hydrocephalus include enlargement (doming) of the cranium if obstruction occurs before the sutures have fused (Fig. 14-40). The bones of the calvarium are extremely thin and the fontanelles are prominent (Fig. 14-41). In the brain there is prominent enlargement of the ventricular system proximal to the point of obstruction (Fig. 14-42). White matter adjacent to the dilated lateral ventricles is reduced in thickness, although the gray matter can retain a relatively normal appearance. As the hydrocephalus progresses, atrophy with fenestration of the interventricular septum (septum pellucidum), atrophy of the hippocampus in the floor of the lateral ventricles, and flattening of cortical gyri can occur. If the obstruction is abrupt and pressure builds rapidly, the cerebral hemispheres can be displaced caudally, causing herniation of the parahippocampal gyri under the tentorium cerebelli and of the vermis of the cerebellum through the foramen magnum. The resulting coning of the cerebellum can be accompanied by necrosis of cells in the cerebellar folia as a result of ischemia and infarction. Microscopically the ependyma can become atrophied and focally discontinuous, and there is loss of cells and cell processes in adjacent white matter and variably in the gray matter.

Fig. 14-40 **Congenital hydrocephalus, brain, calf.** Note the symmetrically enlarged and dome-shaped calvarium. The bone of the calvarium is thinned and distorted from pressure from the expanding brain during gestation. (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

Fig. 14-41 **Calvarium, view of the dorsal surface, congenital hydrocephalus, dog.** The bone of the calvarium is thin and the fontanelles (arrows) are enlarged. The translucent membrane covering the fontanelles is periosteum. (Courtesy Drs. J. Wright and D. Duncan, College of Veterinary Medicine, North Carolina State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Clinically, congenital hydrocephalus occurs most frequently in brachycephalic or toy breeds such as the Chihuahua, Lhasa apso, and toy poodle. Clinical signs occur within the first year of life, often before 3 months of age. Behavioral changes are the most common and include poor motor skill development; delay in learned behavior, such as house training; somnolence; dullness; episodic confusion; circling; periodic aggression; and seizures.

874

875

**Fig. 14-42 Hydrocephalus, brain, dog.** **A**, Midsagittal section of the head, third ventricle. Note the dilated third and lateral ventricles and the absence of most of the septum pellucidum between the left and right lateral ventricles. **B**, Junction between parietal and occipital lobes, level of thalamus. Bilateral dilation of lateral ventricles dorsally (LV), and ventrolaterally. The fornix has separated and lies on the flattened floor of the ventricle. Note that the third ventricle (TV) and junctional area between the third ventricle and mesencephalic aqueduct (TV-MA) are not enlarged and are possibly even reduced in size, suggesting that the obstruction may be at, or rostral, to this plane of section. (**A**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy Dr. R. Storts, College of Veterinary Medicine, Texas A&M University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

14.1.2.1.6.2

### Acquired Hydrocephalus

Noncommunicating acquired hydrocephalus has been associated with injury of the ependyma, resulting in obstruction of any of the following: the lateral apertures of the fourth ventricle, the cerebral aqueduct, or the interventricular foramen. Causes of obstruction include compression by cerebral abscesses and neoplasms, and blockages by infectious/inflammatory disease resulting in a ventriculitis and, uncommonly, by cholesteatomas in the choroid plexus of the lateral ventricles of the horse. Because the calvarium has now ceased to grow, unlike congenital hydrocephalus, it is of normal size and shape, and its bone is of normal thickness.

A second type of acquired hydrocephalus, referred to as hydrocephalus ex vacuo (or compensating hydrocephalus), usually occurs in the cerebral hemispheres secondary to loss of neural tissue. If there is loss of neurons in the cerebral cortex, as in bovine polioencephalomalacia or other types of laminar cortical necrosis, the axons of these neurons, which normally traverse the white matter of the cerebral hemispheres, will disappear by Wallerian degeneration, and there will be atrophy of the cortex from the loss of neuronal cell bodies and of the white matter from the loss of axons. The lateral ventricles will expand into the space once occupied by white matter. This dilatation of the lateral ventricles may be bilateral when there has been a loss of white and gray matter from both cerebral hemispheres, or it may be unilateral. If the loss of cortex is localized, as in an infarct, then dilatation of the lateral ventricle will not uniformly involve the whole lateral ventricle. Examples of disorders in which hydrocephalus ex vacuo occur include some storage diseases (ceroid-lipofuscinosis in sheep), aging, and postradiation exposure, all of which are associated with cerebral atrophy. There is no evidence of obstruction of the normal flow of CSF in this type of hydrocephalus.

14.1.2.2

### DISEASES CAUSED BY MICROBES

14.1.2.2.1

#### BACTERIA

14.1.2.2.1.1

#### Brain Abscesses

Cerebral abscesses in animals are relatively uncommon but arise following entry of bacteria into the CNS. This may occur either from direct extension or hematogenously. With direct extension, abscesses occur following penetrating wounds, such as calvarial fractures, or from spread of infection from adjacent tissues, such as the leptomeninges, paranasal sinuses, and internal ear, and through the cribriform plate of the ethmoid (Fig. 14-12). Diseases that cause bacteremia or septicemia result in infectious agents being trapped in vascular beds within the CNS and meninges. Abscesses usually arise within gray matter because it receives a disproportionate share of blood flow in the CNS, usually at the gray-white (cortex-subcortical white matter) junction. They exert effects in the CNS by disruption and destruction of tissue and by displacement as space-occupying lesions. If the abscess grows quickly, tissue is more likely to be disrupted and destroyed and in the worst case penetrate the wall of the lateral ventricle and cause a ventriculitis. Bacteria in the CSF may be carried into the subarachnoid space and cause a leptomeningitis. On the other hand, if growth is slow, tissue is more likely to be displaced. Chronic abscesses become encapsulated by either fibrous tissue if they are close to the leptomeninges or by astrocytes away from the meninges. The mechanism of tissue injury is likely a secondary bystander effect related to the actions of the mediators of inflammation and the toxins and other products elaborated from bacteria. Bacteria appear to localize in specific areas of the CNS based on

875

876

## Pathologic Basis of Veterinary Disease, 4th Edition

receptor-mediated attachment or because of vascular flow patterns unique to the gray matter–white matter interface of the CNS that allows bacteria to attach to and move through the blood-brain barrier. This latter flow mechanism likely occurs because small blood vessels supplying the cerebrum fail to continue into the white matter and end with their horizontal branches running parallel to the surface of the gyrus within the gray matter at the interface with the white matter. Once within the CNS or meninges, bacteria replicate and elicit an inflammatory response. Lytic enzymes released from lysosomes of neutrophils and other inflammatory cytokines secreted by lymphocytes and macrophages destroy neurons and their processes and disrupt synapses, thus affecting neurotransmission.

Grossly, brain abscesses can be single or multiple, be discrete or coalescing, and have varied sizes (Fig. 14-43). Early in the process, abscesses consist of a white to gray to yellow, thick to granular exudate. The color of the exudate can be influenced by the exuberance of the pyogenic response elicited by the inciting bacteria and by any pigments produced by the bacteria. *Streptococcus* spp., *Staphylococcus* spp., and *Corynebacterium* spp. may produce a pale-yellow to yellow, watery to creamy exudate. Coliforms, such as *Escherichia coli* and *Klebsiella* spp., may produce a white to gray, watery to creamy exudate. *Pseudomonas* spp. may produce a green to bluish-green exudate. The borders of abscesses are often surrounded by a red zone of active hyperemia induced by inflammatory mediators acting on capillary beds. With chronicity, abscesses may be walled off by processes of astrocytes and fibrous connective tissue from the pia mater, especially when the abscess results from a penetrating wound.

**Fig. 14-43 Chronic cerebral abscesses, sheep.** Abscesses with caseous centers (arrow) have replaced most of the right cerebral hemisphere, enlarged it, and displaced the midline to the left. The abscesses are encapsulated by a thick fibrous capsule generated by fibroblasts of the pia and perivascular spaces of the outer cortex. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Brain abscesses can arise in some food animal species from an extension of otitis interna (Figs. 14-12 and 14-32). These animals often display evidence of facial nerve paralysis, such as a drooping ear. The

## Pathologic Basis of Veterinary Disease, 4th Edition

cerebellopontine angle and adjacent structures are the common locations for such abscesses. In horses, *Streptococcus equi* (strangles) can cause brain abscesses via hematogenous spread from lymphoid tissues (Fig. 14-44). Direct penetration may also occur in small ruminants that lack frontal sinuses because of improper dehorning procedures. Brain abscesses are space-occupying lesions and as such can have a devastating effect on brain function. Depending on size and location, compression via mass effect (increased intracranial pressure) of vital structures (nuclei that regulate cardiac and respiratory rhythms) and brain displacements (cerebellar vermis, parahippocampal gyri) are two common sequelae to acute abscesses. Abscesses can occur in the spinal cord as a result of direct extension of bacterial vertebral osteomyelitis through the dura (Fig. 14-45), following tail docking in lambs, and occasionally from hematogenous spread.

876

877

**Fig. 14-44 Abscess, right cerebral hemisphere, horse.** The cerebral cortex contains an abscess (*arrow*) caused by *Streptococcus equi* entering the central nervous system via the blood (strangles). A fibrous capsule is present on the lateral, medial, and dorsal sides of the abscess (most obvious on the lateral side as a gray band). There is no obvious capsule present on the ventral side (i.e., toward the right lateral ventricle). Microscopically, there would be a thin glial capsule (astrogliosis). Note also the increased size of the right hemisphere with blurring of the distinction between gray and white matter, an indication of edema. Scale bar = 2 cm. (Courtesy Dr. K. Read, College of Veterinary Medicine, Texas A&M University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

**Fig. 14-45 Diskospondylitis, thoracic spinal cord, pig.** This type of abscess (*arrows*) is commonly caused by bacterial emboli that lodge in intervertebral disks or in the body of vertebrae causing osteomyelitis, which can extend into intervertebral disks. Large intervertebral abscesses can compress the spinal cord and cause Wallerian degeneration of nerves, mainly in the ventral funiculi but also in other funiculi. In this case, remodeling and proliferation of the vertebral bone secondary to the infection also contributed to the narrowing of the spinal canal and compression of the spinal cord. (*Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

Clinically, animals with brain abscesses can show abnormal mental behaviors, ataxia, head tilt, circling, and loss of vision.

### 14.1.2.2.1.2

#### Diffuse Encephalitis

Common bacteria have the potential to produce disease in the CNS by hematogenous spread and vasculitis. Also see Neonatal Septicemia.

### 14.1.2.2.1.3

#### Ependymitis and Choroid Plexitis

Infectious agents, especially pus-forming bacteria, such as the coliform and *Streptococcus* spp., can enter the CNS hematogenously or via direct extension, invade the choroid plexuses, and be released into the CSF, gaining access to ependymal cells lining the ventricular system. Inflammation of the

## Pathologic Basis of Veterinary Disease, 4th Edition

---

ependyma is called ependymitis, whereas inflammation of the choroid plexus is called choroid plexitis. Gross lesions usually consist of gray-white to yellow-green thick to gelatinous CSF within the ventricular system and choroid plexuses that are granular and gray-white, with areas of active hyperemia and hemorrhage. If the bacteria traverses through the lateral apertures of the fourth ventricle, they can enter and spread throughout the subarachnoid space, possibly inducing suppurative bacterial leptomeningitis. The exudate can also obstruct CSF flow, leading to noncommunicating hydrocephalus. Microscopically, inflammatory cells, especially neutrophils, mixed with fibrin, hemorrhage, and bacteria, can be seen in the exudate.

14.1.2.2.1.4

### Listeriosis

Listeriosis, a bacterial disease with particular affinity for the CNS, is seen mainly in domestic ruminants. There is compelling evidence that *Listeria monocytogenes*, a facultative intracellular gram-positive bacterium, invades through the mucosa of the oral cavity and into sensory and motor branches of the trigeminal nerve. Other cranial nerve branches that innervate the oral cavity and pharynx may also be involved. The bacteria migrate via sensory axons using retrograde axonal transport to the trigeminal ganglion and then into the brain (medulla) or via motor axons directly to the midbrain and medulla (motor neurons—nucleus of cranial nerve V). The infection can then spread rostrally and caudally to other areas of the brain stem. Lesions are occasionally found in the cerebellum and cranial cervical spinal cord. These sites are likely the result of direct extension of infection because *Listeria monocytogenes* is a motile bacterium that spreads from cell to cell in its replicative phase.

The mechanism of tissue injury is not completely defined; however, injury to neurons and axons is likely a secondary bystander effect related to inflammation. A correlation between the degree of cell-mediated immunity and severity of brain damage suggests that immunologic injury may occur. Recent studies in a murine model, however, indicate the T lymphocyte response is only slight in early stages of fatal listeriosis. Immunization before experimental infection enhances CD4<sup>+</sup> and CD8<sup>+</sup> T-lymphocyte responses and provides greater survivability. Other studies have shown increased production of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukin (IL)-10 in fatal murine infections. The former is capable of causing brain damage (apoptotic cell death) and augmenting other CNS immune responses; the latter has a suppressive effect on neuroimmunologic reactions. The organism also produces a hemolysin (listeriolysin) that is a virulence factor required for intracellular multiplication.

877

Once bacteria enter the CNS, recent experimental studies suggest that *Listeria monocytogenes* can directly infect neurons, microglia, choroid plexus epithelial cells, and macrophages recruited in the inflammatory exudate. The bacteria spread from cell to cell using a secreted phospholipase that cleaves a variety of phospholipids, including sphingomyelin (a component of myelin) and phospholipids in cell membranes. Axonal injury and neuronal death are likely attributable to inflammatory processes, especially to the action of listeriolysin and lipases.

878

Gross lesions are usually absent, but leptomeningeal opacity, foci of yellow-brown discoloration (0.1 to 0.2 mm in diameter in the area of the nuclei of cranial nerves V and VIII), hemorrhage, necrosis in the terminal brain stem, and cloudy CSF have been noted. Microscopically a meningoencephalitis centered about the pons and medulla and involving both gray and white matter is characteristic (Fig. 14-46). The lesions, however, can extend from the diencephalon to the caudal medulla or cranial cervical spinal cord. Small, early lesions consist of loose clusters of microglial cells. With time, these lesions enlarge and contain variable numbers of neutrophils (Fig. 14-46, B) and later neutrophils dominate (microabscesses), but in some foci, macrophages can be the principal cell type. Necrosis and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

accumulation of gitter cells can be prominent in some cases. Numerous gram-positive bacilli can be detected in some lesions (Fig. 14-46, C). Leptomeningitis is regularly present and is often severe, and the exudate is composed of macrophages, lymphocytes, plasma cells, and fewer neutrophils. Cranial ganglioneuritis involving the trigeminal nerve and ganglion is often present.

Listeriosis presents in three disease forms: meningoencephalitis, abortion and stillbirth, and septicemia. The last commonly develops in young animals, possibly from an in utero infection. The encephalitic and genital forms of the disease rarely occur together in an individual animal or in the same flock or herd. Infections in human beings also occur. Clinical signs in meningoencephalitic listeriosis are related to lesions in the brain stem and include dullness, torticollis, circling, unilateral facial paralysis, and drooling caused by pharyngeal paralysis. Signs of cranial nerve dysfunction occur because of inflammation in the medulla and pons. Death usually occurs within a few days after the initial signs and is preceded by recumbency and paddling of the limbs. Silage is the most common source of infection. If silage is contaminated with soil containing *Listeria monocytogenes* and is improperly prepared and stored (pH > 5.4), the organism can multiply.

14.1.2.2.1.5

### Meningitis

*Meningitis* refers to inflammation of the meninges (Fig. 14-47). In animals, meningitis is most commonly caused by bacteria such as *Escherichia coli* and *Streptococcus* spp. that traverse to the leptomeninges and subarachnoid space hematogenously. Bacteria can also spread to the meninges by direct extension and leukocytic trafficking. In common usage, the term *meningitis* generally refers to inflammation of the leptomeninges (the pia mater, subarachnoid space, and adjacent arachnoid mater) in contrast to inflammation of the dura mater, which is referred to as pachymeningitis. Leptomeningitis can be acute, subacute, or chronic and, depending on the cause, suppurative, eosinophilic, nonsuppurative, or granulomatous. Inflammation of specific parts of the dura mater of the cranial cavity can occur in the external periosteal dura following osteomyelitis, formation of extradural abscesses and pituitary abscesses, and skull fracture and involve the inner dura in association with leptomeningitis. Abscesses of the pituitary fossa occur with some frequency in cattle. Bacteria isolated from the cases include *Pasteurella multocida* and *Actinomyces pyogenes*. The abscess can result from spread of infection arising in the caudal nasal cavity or sinuses, possibly through direct extension or through the venous circulation. Incision of the pituitary fossa releases a thick viscous opaque tan to yellow exudate, which can elevate the dura mater surrounding the fossa. Infection can extend via the infundibular recess of the third ventricle into the ventricular system, resulting in ventriculitis, ependymitis, and empyema. Systemic bacterial infections in neonates are a common cause of acute meningitis (leptomeningitis), which are suppurative and fibrinous. In animals, leptomeningitis secondary to a selective viral infection only of the leptomeninges is very rare and is usually seen in combination with viral-induced encephalitides.

878

879

Fig. 14-46 **Listeriosis, medulla, cow.** **A**, Microabscesses. Note the areas of faint blue discoloration in this subgross magnification of the medulla (*arrows*). The less well-defined blue areas are aggregates of neutrophils (microabscesses), and the blue linear lesions are perivascular cuffs. *Listeria monocytogenes*, the causative agent, uses retrograde axonal transport via the cranial nerves to enter the central nervous system and localize in the medulla (brain stem) and proximal cervical spinal cord. The lesion is rarely visible on gross observation. H&E stain. **B**, Early microabscesses (*arrows*) and inflammation are the result of inflammatory mediators that have injured axons (*arrowheads*) and will lead to Wallerian degeneration, seen here at the stage of swollen eosinophilic axons. H&E stain. **C**, *Listeria monocytogenes*. *Listeria monocytogenes*, which is gram-positive (*blue*), can sometimes be detected in microabscesses in a histologic section stained with a Gram stain. Zachary, College of Veterinary Medicine, University of Illinois.)

14.1.2.2.1.6

### Neonatal Septicemia

Neonatal septicemia typically involves *Escherichia coli*, *Streptococcus* spp., *Salmonella* spp., *Pasteurella* spp., and *Haemophilus* spp. The release of endotoxins and bacterial cell wall components, such as lipopolysaccharide (LPS), teichoic acid, and proteoglycans, in the CNS vasculature leads to the secretion of cytokines (TNF, IL, platelet-activating factor, prostaglandins, thromboxane, leukotrienes) from the endothelium and trafficking CNS macrophages, followed by adhesion of neutrophils, injury to the endothelium and blood-brain barrier, and vasculitis resulting initially in brain swelling and brain edema and increased intracranial pressure.

Although there are differences in the diseases caused by these organisms, they tend to produce fibrinopurulent inflammation of membranous tissues (serosal surfaces) of the body. Leptomeninges, choroid plexus, and ependyma of the CNS—sites often preferentially involved in hematogenous spread of bacteria, synovium, uvea, and the serosal lining of body cavities—can be affected in various combinations. Infections are often acquired perinatally, and onset is usually within a few days of birth up to 2 weeks (Table 14-3). The initial portal of entry can be oral, intrauterine, umbilical, surgical, via postsurgical procedures such as castration and ear notching, or via the respiratory system, but the bacteria eventually spread to the CNS hematogenously.

*Salmonella choleraesuis*—leptomeningitis, ophthalmitis

Gross CNS lesions are commonly present and include congestion, hemorrhage, and diffuse to focal cloudiness or opacity in the leptomeninges, resulting in a leptomeningitis due to accumulation of exudates (Fig. 14-47). The ventricles contain fibrin, usually as a thin layer on the ependymal surface or as a pale coagulum in the CSF of the ventricular lumen, secondary to a choroid plexitis and/or ependymitis.

Microscopic lesions vary according to the organism. With the exception of *Salmonella* spp., the lesions consist of deposits of fibrin and an infiltration of mainly neutrophils in and around the blood vessels and capillaries of the leptomeninges, choroid plexus, and ependymal or subependymal areas of the

brain. The epithelium of the choroid plexus and ependymal lining of the ventricles can be disrupted by cellular degeneration, disorganization, and necrosis, and this inflammation can extend into the adjacent CNS. A vasculitis with thrombosis and hemorrhage can be associated with lesions caused by *Escherichia coli*. Lesions caused by *Salmonella* spp. are not limited to the perinatal period. CNS involvement in salmonellosis is generally limited to foals and pigs and in contrast to the above infections, the leukocytic response tends to have a greater proportion of macrophages and lymphocytes, often to the extent that the inflammation is designated histiocytic or granulomatous. This difference presumably reflects the fact that *Salmonella* spp. can be facultative pathogens of the monocyte-macrophage system. As is true in other tissues, vasculitis, thrombosis, necrosis, and hemorrhage often accompany *Salmonella* infections of the CNS. *Haemophilus parasuis*, which causes Glasser's disease, is also a frequent cause of leptomeningitis, polyserositis, and polyarthritis in 8- to 16-week-old pigs. Again, lesions are as previously noted with fibrinopurulent inflammation involving the leptomeninges, serosal linings of body cavities, and joints.

Bacterial infection with CNS and visceral involvement occurs in neonatal pigs and through the weaning period. These diseases are deserving of special mention because of the incidence and stereotyped nature of the infections. Several strains of *Streptococcus suis* are capable of causing disease. Type 1 strains generally cause disease in suckling pigs ranging in age from 1 to 6 weeks, whereas type 2 strains affect older pigs 6 to 14 weeks old. Type 2 strains are recognized as one of the more important serotypes, causing meningitis not only in pigs but also in human beings, particularly those working with pigs or handling porcine tissues. Other serotypes and untypeable strains can also cause systemic disease that results in leptomeningitis, choroid plexitis, and ependymitis. Extension to involve cranial nerve roots or the central canal of the cervical spinal cord also occurs. The character of the inflammation is fibrinopurulent, and necrotic foci can be found in brain stem, cerebellum, and anterior spinal cord.

Clinically, affected animals are initially ataxic, and then become laterally recumbent with rhythmic paddling of the limbs. As the disease progresses, they may become comatose and die.

### 14.1.2.2.1.7

#### Thrombotic Meningoencephalitis

*Histophilus somni* (formerly *Haemophilus somnus*), a small gram-negative bacillus, causes a septicemic infection in cattle with variable clinical presentations, including pneumonia, polyarthritis, myocarditis, abortion, and meningoencephalitis. The disease is most prevalent in feedlot cattle but can occur in other situations. All manifestations, particularly meningoencephalitis, tend to be sporadic with single to multiple animals in a herd affected. The CNS form of the disease has been termed thrombotic meningoencephalitis (TME), previously referred to as thromboembolic meningoencephalitis (TEME). Mural thrombi from local vascular injury rather than thromboemboli from distal sites of vascular injury, such as the lungs, are the major type of thrombus in this disease.

880

The pathogenesis of *Histophilus somni* (formerly *Haemophilus somnus*) infection is not completely understood. Many cattle harbor the organism in the upper digestive tract without evidence of disease, but under some circumstances it invades to cause severe clinical infection. The mechanism(s) of invasion into the blood stream is not definitely known, but the respiratory tract is the initial site of bacterial replication followed by hematogenous spread to the CNS. Once the bacteria gain access to the circulation (bacterial emboli), emboli lodge at the interface of the gray and white matter in microvessels. Organisms adhere to endothelial cells, presumably via a receptor-mediated interaction, which results in endothelial cell contraction and desquamation. Subendothelial collagen is exposed, initiating a cascade of events culminating in vasculitis, thrombosis, and infarction. The bacteria within the infarct replicate and cause inflammation. Lipooligosaccharide, a toxic factor produced by

881

## Pathologic Basis of Veterinary Disease, 4th Edition

---

*Histophilus somni* (formerly *Haemophilus somnus*) might protect the bacteria from host defenses. Bovine neutrophils, blood monocytes, and alveolar macrophages are incapable of killing the organism, allowing the infection to become established.

Gross lesions in the CNS are irregularly sized foci of hemorrhage and necrosis scattered randomly, and visible both externally and on cut surfaces (Fig. 14-48). Lesions are most frequent in the cerebrum, commonly at the cortical gray matter–white matter interface. The location of the lesion may reflect a change in the diameter and flow patterns of blood vessels, allowing bacteria to lodge, adhere, and replicate in these vessels. The spinal cord also has lesions. Other lesions include brain swelling due to edema and leptomeningitis with cloudiness of the CSF.

Microscopic lesions in all organs including the CNS are initially marked vasculitis and vascular necrosis, which are followed by thrombosis and infarction. Septic vasculitis, the initial event, is followed by edema and an influx of neutrophils and macrophages in and around vessel walls and adjacent parenchyma. Colonies of small gram-negative bacilli are frequent in thrombi, in and around affected vessels, and in areas of necrosis.

Clinically, affected cows are initially ataxic and circle, head-press, and appear blind. As the disease progresses, they may have convulsions, become comatose, and die.

### 14.1.2.2.2 VIRUSES

The viruses causing CNS disease in domestic animals are listed in [Table 14-4](#).

### 14.1.2.2.2.1 Arboviruses

#### 14.1.2.2.2.1.1 Equine encephalomyelitis

Eastern, western, or Venezuelan equine encephalomyelitis (EEE, WEE, VEE) viruses are members of the family *Togaviridae*, genus *Alphavirus*. The primary target cell for infection and injury is the neuron; however, these viruses can cause vasculitis followed by thrombosis. Following inoculation (by mosquito), the hematogenously circulating virus initially infects several tissues, including bone marrow, lymphoreticular tissue, muscle, and connective tissue. In lymphoid tissue and bone marrow, this infection may cause cellular depletion, necrosis, or both. A second viremia results in hematogenous infection of the CNS. Experimental evidence suggests that the virus replicates in endothelial cells before entering the nervous system and infecting neurons, for which it has an affinity. There is also evidence that viruses of this group (VEE virus) can cause alterations in the metabolism of neurotransmitters in the CNS and that these alterations are responsible for some of the clinical signs.

**Fig. 14-48 Thrombotic meningoencephalitis (previously referred to as thromboembolic meningoencephalitis), cerebrum, steer.** On the surface of the cerebral cortex (*arrows*) are several red-brown lesions. These lesions are areas of necrosis, hemorrhage, and inflammation secondary to vasculitis and thrombosis caused by *Histophilus somni* (formerly *Haemophilus somnus*). Such septic infarcts are distributed randomly (hematogenous portal of entry) throughout the central nervous system, including the spinal cord. The lesions depicted here are unusually severe. (Courtesy Dr. H. Leipold, College of Veterinary Medicine, Kansas State University.)

Recent experimental evidence from in vivo and in vitro models of VEE suggests that the virus causes upregulation of multiple proinflammatory genes including inducible nitric oxide synthase (iNOS) and TNF- $\alpha$ . This upregulation, occurring principally in astrocytes, affected other glial cells and influenced neuronal survival. In addition to these mediators of innate immune responses, apoptotic cell death was also described as contributing to neurodegeneration following virus infection.

In the CNS, all three viruses induce a polioencephalomyelitis that has similar characteristics, but there are some differences. Overall, gross lesions include cerebral hyperemia, edema, petechiation, focal necrosis, and increased CSF in the subarachnoid space. Gross lesions are usually found in gray matter as appreciated best in the spinal cord (Fig. 14-49). Microscopic lesions are most prominent in the gray matter of the brain and spinal cord and are characterized by perivascular cuffing with lymphocytes, macrophages, and neutrophils, variable neutrophilic infiltration of the gray matter, microgliosis, neuronal degeneration, focal cerebrocortical necrosis, perivascular edema and

881

882

## Pathologic Basis of Veterinary Disease, 4th Edition

hemorrhage, necrotizing vasculitis, thrombosis, choroiditis, and leptomeningitis. Neutrophils are detectable during the early stages (2 days) of clinical EEE and VEE. Vasculitis, thrombosis, and cerebrocortical necrosis are particularly evident in VEE but also in EEE. No lesions are detected in the trigeminal ganglion.

14.1.2.2.1.4

West Nile viral encephalomyelitis

West Nile virus, a mosquito-borne virus (family *Flaviviridae*, genus *Flavivirus*) that causes acute poliomyelitis primarily in human beings, birds, and horses, is most commonly transmitted via a bird-mosquito cycle. In 2002, West Nile virus infection was diagnosed in 47,000 horses in 40 U.S. states and it was estimated that more than 4500 horses died following infection.

882

Fig. 14-49 **Neuronal necrosis and vasculitis, eastern equine encephalomyelitis, brain stem and spinal cord, horse.** **A**, Brain, transverse section at the level of the hippocampus, horse. The gray matter of the brain stem has dark red to black discoloration as a result of congestion and hemorrhage. The lesion is the result of viral infection, which has an affinity for neurons; this virus also causes vascular necrosis followed by thrombosis, but this is not common. **B**, Spinal cord, horse. Note the red to brown discoloration of the gray matter in the dorsal and ventral horns (due to congestion and hemorrhage). The lesion is the result of viral infection that has an affinity for neurons; however, this virus can also cause vascular necrosis followed by thrombosis. (**A** and **B**, Courtesy College of Veterinary Medicine, University of Florida; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The pathogenesis of West Nile virus encephalomyelitis remains to be elucidated; however, it is likely to be similar to the mechanism described previously for equine encephalomyelitis viruses. The primary target cell for infection and injury appears to be the neuron; microglial cells are also affected. Experimental studies suggest that viral-induced apoptotic cell death is a mechanism possibly responsible for neuronal injury in experimental West Nile viral infections. Gross lesions of West Nile viral infection in horses usually involve the gray matter and include hyperemia and petechiation to prominent hemorrhage with prevalent involvement of the lower brain stem and ventral horns of the thoracolumbar spinal cord. Microscopic lesions in birds and horses that have died of the disease are characterized by a nonsuppurative (lymphocytic/histiocytic) polioencephalomyelitis and hemorrhage of the CNS that can vary in degree of severity. Clinical signs of the equine West Nile viral infection include variable fever, depression, ataxia, weakness to paralysis of the hind limbs, tetraplegia, convulsions, coma, and death.

14.1.2.2.2.2

### Coronaviruses

14.1.2.2.2.1

### Feline infectious peritonitis

Feline infectious peritonitis (FIP), which is caused by a coronavirus and has a worldwide distribution, is mainly a disease of domestic cats, although wild Felidae can be affected. There are two recognized feline coronaviruses (FCoV): feline enteric coronavirus (FECV) and feline infectious peritonitis virus (FIPV), which cause FECV and FIP infections, respectively. The viruses for each infection are antigenically and morphologically indistinguishable and are currently considered to represent avirulent (FECV) and virulent (FIPV) strains of the same basic FCoV virus. Following ingestion, FECV infects and replicates in epithelial cells of the intestine and usually is an insignificant infection, although severe intestinal disease can occur. It has been proposed that when FECV gains the ability (by mutation) to replicate in macrophages, then FIP can occur.

The FIP virus (FIPV) enters the susceptible cat primarily by ingestion of contaminated saliva or feces, although transmission by direct inoculation (cat bites, licking open wounds, etc.) and in utero (rarely) have been reported. Following infection, the virus replicates in macrophages that spread the virus to the liver, visceral peritoneum and pleura, uvea, and the meninges and ependyma of the brain and spinal cord.

Following dissemination of the virus in the body, the development of disease depends on the type and degree of immunity that develops. Virus containment with resistance to disease occurs following development of a strong cell-mediated immunity. Humoral immunity by itself is not protective and can actually enhance development of the effusive form of FIP (wet form) by two proposed mechanisms. The first involves the development of virus-antibody-complement complexes that particularly accumulate in the same areas as infected macrophages around small blood vessels, resulting in inflammation and subsequent vascular injury (type III hypersensitivity) accompanied by effusion of large amounts of fluid. The second mechanism involves a process referred to as antibody-dependent enhancement (demonstrated to occur experimentally), which involves uptake of virus-antibody-complement complexes by macrophages followed by significant viral replication. 883

The heavily infected macrophages, frequently perivascularly orientated, release cytokines that result in alteration of endothelial junctional complexes that leads to leakage of substantial amounts of fluid. 884

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Noneffusive FIP (i.e., dry form), in comparison, is thought to occur when partial cell-mediated immunity (type IV hypersensitivity) develops and represents an intermediate stage between nonprotective humoral immunity alone and protective cellular immunity. Support for this mechanism is the fact that cats that develop the noneffusive form of FIP following experimental infection usually have a preceding and transient bout of effusive-type disease. In addition, there is evidence to support the theory that cats recovered from FIP are immune by a process of “infection immunity” or “premunity.” Once these cats no longer retain such infections, they seem to also lose protective (cell-mediated) immunity and are, in fact, more sensitive to a subsequent challenge exposure because of the presence of humoral antibody.

The basic lesion in effusive and noneffusive FIP is a pyogranulomatous inflammation, leading to vasculitis followed by an inconsistent vascular necrosis resulting in infarction. The effusive form is typified by serositis, accumulation of fluid in the abdominal and thoracic cavities, with varying degrees of severity of inflammation. Lesions of the noneffusive form more frequently result in leptomeningitis, chorioependymitis, focal encephalomyelitis, and ophthalmitis, although involvement of the kidneys, hepatic and mesenteric lymph nodes, and less frequently, serosa and other abdominal viscera can occur. In the CNS, pyogranulomatous vasculitis tends to affect blood vessels of (1) the leptomeninges, especially in sulci and near their entrance into subjacent CNS tissue and around the circle of Willis (Fig. 14-50) and (2) the periventricular white matter, especially around the fourth ventricle (Fig 14-51). The uvea, retina, and optic nerve sheath are also commonly involved in FIP.

FIP generally occurs sporadically in cats of all ages, but it is most common in younger cats between the ages of 3 months and 3 years and can be clinically significant because it can result in death. The disease manifests itself in effusive (wet) or noneffusive (dry) forms. Clinical signs caused by involvement of blood vessels in the CNS can include behavioral changes, dullness, coma, paresis, ataxia, paralysis, and seizures.

Fig. 14-50 **Pyogranulomatous vasculitis, feline infectious peritonitis, cat.** **A**, Ventral brain, cerebral vasculature of the circle of Willis. A white-yellow pyogranulomatous inflammation distorts and obscures the blood vessels. Lesions are attributed to deposition of immune complexes (type III hypersensitivity), and in some cases possibly with a cell-mediated component, in the vessel walls that results in inflammation (*arrows*). The character of the inflammatory response can vary from an exudate with accumulation of serous fluid and fibrin mixed with neutrophils and histiocytes to a reaction that is more pyogranulomatous, and in which commonly there are lymphocytes and plasma cells. The severity and magnitude of the lesion depicted here is much more dramatic than usual. **B**, A cross-sectional view of Fig. 14-50, **A**. The pyogranuloma (*arrows*) is principally in the subarachnoid space and has compressed the adjacent cerebral cortex. (**A** and **B**, Courtesy Dr. J. Sundberg, College of Veterinary Medicine, University of Illinois.)

14.1.2.2.2.4

### Herpesviruses

Encephalitic herpes viruses, members of the subfamily Alphaherpesvirinae, cause cell injury through: (1) necrosis of infected neurons and glial cells, (2) necrosis of infected endothelial cells, and (3) secondary effects of inflammation, cytokines, and chemokines. Although necrosis appears to be the principal mechanism for cell injury, recent studies indicate that bovine herpesvirus-induced apoptotic cell death can occur.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Neurotropic herpes viruses enter the CNS principally by retrograde axonal transport; however, entry by hematogenous spread via viremia and leukocytic trafficking may occur. These viruses also have a unique survival mechanism that allows them to hide in a latent form in nervous tissue, for example, in trigeminal ganglion of pigs infected with pseudorabies virus. Stress or other factors can activate latent virus resulting in encephalitis.

14.1.2.2.2.4.1

### Bovine malignant catarrhal fever

Malignant catarrhal fever is usually a sporadic highly fatal disease of cattle and other ruminants, including deer, buffalo, and antelope, and can involve several animals in a herd. The disease has a worldwide distribution, and the clinicopathologic features do not differ significantly from one part of the world to another. The primary target tissues are the vasculature and lymphoid organs and epithelial tissue (particularly the respiratory and gastrointestinal tracts), but the kidneys, liver, eyes, joints, and CNS are also affected in some cattle. The virus appears to be transferred between lymphoid tissue/cells and endothelial cells via leukocytic trafficking in T lymphocytes. Two general types of the disease occur, the sheep-associated and wildebeest-derived forms. The causative agents involved belong to the herpesvirus subfamily Gammaherpesvirinae. The disease occurring outside Africa, caused by ovine herpesvirus 2 (OHV-2), often involves close contact of presumed “carrier” sheep with susceptible ruminants. The disease has recently been reported in muskox (*Ovibos moschatus*), Nubian ibex (*Capra nubiana*), and gemsbok (*Oryx gazella*). In Africa, and occasionally in wildlife facilities outside the continent, the source of the infection (designated alcelaphine herpesvirus 1 or AHV-1) is the wildebeest. Two other antigenically related viruses, which apparently do not cause natural disease, include alcelaphine herpesvirus 2 (AHV-2) and hippotragine herpesvirus 1 (HiHV-1), which have been isolated from African hartebeest and roan antelope, respectively. It is generally accepted that cattle and other susceptible ruminants contract the disease in nature following respiratory or oral infection during association with carrier sheep (presumed) and wildebeest, particularly at the time of parturition. A cell-mediated and cytotoxic lymphocytic process has been proposed to be involved in the development of the necrotizing vasculitis.

885

Gross lesions of the CNS include active hyperemia and cloudiness of the leptomeninges due to nonsuppurative meningoencephalomyelitis and vasculitis. Lymphocytic perivascular cuffing and varying degrees of necrotizing vasculitis occur in the leptomeninges and in all parts of the brain and occasionally in the spinal cord, with the white matter most consistently involved. Other lesions in the affected CNS include variable neuronal degeneration, microgliosis, choroiditis, necrosis of ependymal cells, and ganglioneuritis. Clinical signs referable to CNS infection may include trembling, shivering, ataxia, and nystagmus.

886

14.1.2.2.2.4.2

### Infectious bovine rhinotracheitis

Although bovine herpesvirus 1 (BHV-1) occasionally causes a nonsuppurative meningoencephalitis, primarily in young cattle, two variants of BHV-1 isolated in Argentina and Australia (referred to as BHV-1, subtypes 3a and 3b, respectively) and recently BHV-5 (isolated in South America, mainly Argentina and Brazil) have a particular tropism for the CNS. Recent evidence suggests that BHV-5 uses an intranasal route to infect and replicate in the nasal mucosa and then enters the CNS by retrograde axonal transport using the trigeminal and olfactory nerves.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Gross lesions are nonspecific and include meningeal congestion and petechiation in ventral areas of the brain. Microscopic lesions consist of lymphomonocytic meningoencephalitis (nonsuppurative) with the occasional presence of neutrophils. Other changes include neuronal degeneration, vasculitis, focal malacia, and presence of intranuclear acidophilic inclusions in neurons and astrocytes.

Clinically, outbreaks of disease occur in young cattle ranging in age from 5 to 18 months. Lesions can also involve the eyes (conjunctivitis) and tissues of the reproductive, alimentary, and integumentary systems in addition to the nervous system.

### 14.1.2.2.4.3

#### Pseudorabies

Pseudorabies virus (porcine herpesvirus 1), an alphaherpesvirus, causes encephalitis primarily in pigs; several species of domestic and wild animals are also susceptible. The disease is also known as Aujeszky's disease and "mad itch." Pseudorabies is not related to rabies but was named because its clinical signs sometimes resemble those seen with rabies.

The route of natural infection in pigs is intranasal, pharyngeal, tonsillar, or pulmonary by direct contact or aerosolization, followed by reproduction of virus in epithelial cells of the upper respiratory tract. The virus then travels to the tonsil and local lymph nodes by way of the lymph vessels. Following replication in the nasopharynx, virus invades sensory nerve endings and is then transported in axoplasm via the trigeminal ganglion and olfactory bulb to the brain. The virus has also been reported to be capable of spreading transsynaptically. Recent studies have additionally shown that some strains produce lesions in the gastrointestinal tract and myenteric plexuses, suggesting that infection might spread from the intestinal mucosa to the CNS via autonomic nerves. In latently infected pigs, the oronasal epithelium can be recurrently infected by virus spreading from the nervous system, followed by its excretion in oronasal fluid. The mechanisms that allow for latency and recrudescence are unclear, but neuronal apoptosis may play a role. The virus can also spread hematogenously, although in low titer, to other tissues of the body. Cellular attachment, entry, and cell-to-cell spread of the virus are mediated by glycoprotein projections that extend from the surface of the viral particle.

Gross lesions in pigs occur in several nonneural tissues including organs of the respiratory system, lymphoid system, digestive tract, and reproductive tract. Focal tissue necrosis also occurs in the liver, spleen, and adrenal glands, particularly in young suckling pigs, and mortality can be high. The CNS is free of gross lesions except for leptomeningeal congestion. Microscopic lesions in pigs are characterized by a nonsuppurative meningoencephalomyelitis with trigeminal ganglioneuritis. Injury to CNS tissue can be marked, with neuronal degeneration and necrosis. Intranuclear eosinophilic inclusion bodies are not commonly detected in pigs but can be present in neurons, astrocytes, oligodendroglia, and endothelial cells. In cattle, sheep, dogs, and cats, the pathogenesis involving axonal spread to the CNS is comparable to that of pigs, with lesions that include nonsuppurative encephalomyelitis accompanied by ganglioneuritis. Intranuclear inclusion bodies, either eosinophilic or basophilic in their staining characteristics, have been described in neurons of the brain.

The disease in susceptible species other than pigs is generally fatal. Although pigs—particularly young, suckling piglets—can die from infection, most mature pigs remain persistently infected and act as latent carriers. Infection of secondary hosts, such as cattle, sheep, dogs, and cats, regularly involves direct or indirect contact with pigs. Secondary hosts acquire the virus through ingestion,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

inhalation, and wound infection. Dogs and cats often acquire the virus by ingesting organs from pigs that contain the pseudorabies virus.

14.1.2.2.4.4

### Equine herpesvirus 1 myeloencephalopathy

Equine herpesvirus 1 (EHV-1) (an alpha-herpesvirus) is an important cause of equine abortion and perinatal foal infection and death, in addition to myeloencephalitis. EHV-1 can also cause rhinopneumonitis. EHV-1 does not appear to be neuronotropic, which is in contrast to some herpesvirus encephalitides of other species in which the virus replicates in neurons (herpes simplex viral infection in the human, infectious bovine rhinotracheitis viral infection in calves, and pseudorabies viral infection in pigs). In addition to vasculitis being the principal lesion, the infection in the horse also differs somewhat from most other herpetic infections of the CNS in being primarily a disease of the adult, although young animals can be affected.

Equine herpesvirus myeloencephalopathy begins with inhalation of the EHV-1. The virus infects epithelial cells of the nasopharynx and spreads to local lymphoreticular tissue, where it infects lymphocytes and macrophages (monocytes). Through leukocytic trafficking by macrophages (monocytes), EHV-1 is transferred to endothelial cells of the CNS.

The neurologic disease has been experimentally reproduced by intranasal inoculation of the virus (EHV-1, subtype 1), which can replicate in the epithelium of the respiratory or intestinal tracts following infection. Intracellular inclusions occur in the nasal mucosa. Infection of mononuclear leukocytes (predominantly, but not exclusively, T lymphocytes and macrophages) then occurs and is followed by a cell-associated viremia. The virus, which is endotheliotropic, even though infection of neurons and astrocytes can occur, localizes in small arteries and capillaries of the CNS and some other tissues following direct spread from the circulating infected cells. Inflammation of endothelial cells then results in vasculitis leading to thrombosis and infarction of the neural tissue supplied by the thrombosed vessel. Latent infection of the trigeminal ganglion and lymphoid tissues can also occur.

886

887

The characteristic lesion in the CNS caused by EHV-1 infection is a vasculitis affecting endothelial cells of small blood vessels with thrombosis and resulting in focal CNS necrosis (infarction). Lesions occur in both the gray and white matter of the spinal cord, medulla oblongata, mesencephalon, diencephalon, and cerebral cortex (Fig. 14-52, A). The endothelium appears to be the initial site of involvement (Fig. 14-52, B), with the subsequent intimal and medial degeneration resulting in hemorrhage, thrombosis, extravasation of plasma proteins into the perivascular space, axonal swelling with ballooning of the myelin sheath and degeneration of the cell body, and variable mononuclear cellular cuffing. Other lesions include cerebrospinal ganglioneuritis and vasculitis in nonneural tissues, including the endometrium, nasal cavity, lungs, uvea of the eye, hypophysis, and skeletal muscle. Inclusion bodies are apparently not observed in CNS lesions.

Fig. 14-52 **Equine herpesvirus 1 myeloencephalopathy, brain, midsagittal section. A, Hemorrhage, brain stem, horse.** Focal or multifocal areas of hemorrhage and/or necrosis (*arrow*) are characteristic of equine herpes virus encephalitis, but also occurs in equine arteritis virus encephalitis, cerebrospinal nematodiasis, and equine protozoal encephalomyelitis (*Sarcocystis neurona*). **B, Vasculitis and hemorrhage, brain stem, horse.** Vasculitis is the principal lesion. The virus localizes in small arteries, venules, and capillaries of the central nervous system, resulting in vasculitis and fibrinoid necrosis which at times leads to thrombosis and focal infarction of the brain and spinal cord. (A, Courtesy College of Veterinary Medicine, University of Illinois. B, Courtesy Dr. J. Simon, College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The neurologic form of EHV-1 infection has a worldwide distribution and affects other Equidae, including zebras in addition to the horse, but appears to be relatively uncommon when compared with the incidence of abortion and upper respiratory tract disease caused by EHV-1. The neurologic disease may accompany or follow outbreaks of respiratory disease or abortion. An outbreak of epizootic acute encephalitis in Thomson's gazelle (*Gazella thomsoni*) was reported in 1997 from a zoological garden in Japan. That disease resembled equine herpesvirus encephalitis, and the virus, named gazelle herpesvirus 1 (GHV-1), was serologically related to EHV-1 and had a strong tropism for endothelium.

See [Appendix 14-1](#).

14.1.2.2.2.6

### Rhabdoviruses

14.1.2.2.2.6.1

#### Rabies encephalitis

Rabies virus (family Rhabdoviridae) is one of the most neurotropic of all viruses infecting mammals. It is generally transmitted by a bite from an infected animal; however, respiratory infection has also been uncommonly reported following exposure to virus in bat caves, accidental human laboratory exposure, and corneal transplants.

The proposed mechanism for spread of rabies virus from the inoculation site to the CNS is illustrated in [Fig. 14-53](#). Rabies virus may first replicate locally at the site of inoculation. Infection of and replication in local skeletal muscle myocytes may be an important initiating event. The virus then enters peripheral nerve terminals by binding to nicotinic acetylcholine receptors at the neuromuscular junction. The probability is greater that the virus will be taken up by both axon terminals and myocytes following a large inoculation dose. If the virus directly enters peripheral nerve terminals, the incubation period will more likely be short regardless of whether muscle cells are infected. With progressively lower doses of virus, however, there is a greater possibility that the virus will enter either nerve terminals or myocytes, but not both. This situation can result in a short incubation period if the virus directly enters nerve terminals as described previously or could result in a more prolonged incubation period if there was initial infection and retention of virus in myocytes before its release and uptake by nerve terminals.

887

888

Fig. 14-53 **Rabies pathogenesis.** Following a bite wound, 1, the rabies virus initially replicates in muscle (can enter peripheral nerves directly), 2, enters, 3, and ascends (retrograde axonal transport) the peripheral nerve 4, to the dorsal root ganglion, 5, enters the spinal cord 6, and ascends 7, to the brain via ascending and descending nerve fiber tracts, infects brain cells, spreads to salivary glands 8, and the eye and is excreted in saliva. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois. Based on an illustration from Robinson PA: Rabies virus. In Belshe RB, editor: Textbook of human virology, ed 2, St Louis, 1991, Mosby.)

The virus moves from the periphery to the CNS by fast retrograde axoplasmic transport, apparently via sensory or motor nerves, at a rate of 12 to 100 mm per day. Experimental data suggest that rabies virus phosphoprotein interacts with dynein LC8, a microtubule motor protein used in retrograde axonal transport. With sensory axons, the first cell bodies to be encountered following inoculation of

## Pathologic Basis of Veterinary Disease, 4th Edition

---

a rear leg would be those of spinal ganglia, whose neuronal processes extend to the dorsal horn of the spinal cord. For motor axons, the cell bodies of the lower motor neurons in ventral horn gray matter, or neuronal cell bodies of the autonomic ganglia, are the ones initially infected. It is not known whether viral infection and replication in neurons of dorsal root ganglia are essential for infection of the CNS. The virus then moves into the spinal cord and ascends to the brain using both anterograde and retrograde axoplasmic flow. During the spread of the virus between neurons within the CNS, there is also simultaneous centrifugal movement via anterograde axonal transport of the virus peripherally from the CNS to axons of cranial nerves. This process results in infection of various tissues, including the oral cavity and salivary glands, permitting transmission of the disease in the saliva. An additionally important feature of rabies is that infection of nervous and nonnervous tissue, such as the salivary glands, occur at the same time, which permits affected animals to have the required aggressive behavior plus passage of the virus into the saliva to facilitate the transmission of the disease.

The results of recent experimental studies have helped clarify the mechanism by which the virus spreads within the CNS. Following axoplasmic spread of the virus from an inoculated rear leg to neurons of the associated segments of the spinal cord, rapid spread of infection to the brain occurs via long ascending and descending fiber tracts, bypassing the gray matter of the rostral spinal cord. This early spread of the virus has been suggested to explain how induction of behavioral changes occurs before there is sufficiently severe injury to cause paralysis and allows dissemination of infection before there is time for a notable immune response. Spread of infection within neurons of the CNS recently has been proposed to occur via both anterograde and retrograde axoplasmic flow, with corresponding neuron-to-neuron spread by axosomatic-axodendritic and somatoaxonal-dendroaxonal transfer of virus. Transsynaptic spread can occur by budding of developing virions from the neuronal cytoplasm (cell body or dendrite) into a synapsing axon or in the form of bare viral nucleocapsid (ribonucleoprotein-transcriptase complexes) in the absence of a complete virion.

In vivo experimental studies using a laboratory strain of rabies virus showed that the virus caused a down-regulation of about 90% of genes in the brain at more than fourfold lower levels. Affected genes were those involved in regulation of cell metabolism, protein synthesis, and growth and differentiation. Other experimental studies have shown increased quantities of nitric oxide in brains of rabies-infected animals, suggesting that nitric oxide neurotoxicity may mediate neuronal dysfunction. Finally, the rabies virus has been shown to induce apoptotic cell death of brain neurons in mouse models. The exact mechanism of rabies virus-induced neuronal injury in domestic and wildlife species remains to be fully determined.

Gross lesions of the infected central nervous tissue are often absent. Microscopic lesions of the CNS are typically lymphomonocytic (nonsuppurative) and include a variable leptomeningitis and perivascular cuffing with lymphocytes, macrophages, and plasma cells; microgliosis which sometimes is prominent; variable, but often not severe, neuronal degeneration; and ganglioneuritis. Occasional and slight infection can also involve the leptomeninges, ependyma, oligodendroglia, and astrocytes. Emphasis should be given to the fact that infected neurons often are minimally altered morphologically. Neurons can also contain intracytoplasmic acidophilic (pale red to red) inclusions called Negri bodies (Fig. 14-54). Also, dogs are reported to have a tendency to develop a more severe inflammatory reaction than other species, such as the cow, in which little if any inflammation might occur. Nonneural lesions include variable nonsuppurative sialitis accompanied by necrosis and presence of Negri bodies in canine salivary epithelial cells.

**Fig. 14-54 Rabies, Negri body, cerebellum, Purkinje cell, cow.** A large pale red (eosinophilic) inclusion (Negri body) is present in the cytoplasm of the neuron cell body (*arrow*). In the cow, Negri bodies are seen in Purkinje cells and in other neurons, such as those of the red nucleus and cerebral cortex. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Negri bodies, formed within neurons of the CNS and even in the cranial trigemina, spinal, and autonomic ganglia, have long been the hallmark of rabies infection, although they are not present in all cases. The inclusions are intracytoplasmic and initially develop as an aggregation of strands of viral nucleocapsid, which rather quickly transforms into an ill-defined granular matrix. Mature rabies virions, which bud from the nearby endoplasmic reticulum, can also be located around the periphery of the matrix. With time, the Negri body becomes larger and detectable by light microscopy. Classically, in H&E stained sections, the Negri body, which is eosinophilic, has one or more small, light clear areas called inner bodies that form as a result of invagination of cytoplasmic components (that include virions) in the matrix of the inclusion. Inclusions that do not possess “inner bodies” have been referred to as Lyssa bodies, but they are actually Negri bodies without cytoplasmic indentation. It should also be noted that both fixed viruses (adapted to the CNS by passage) and street viruses (that produce the naturally occurring disease) produce the same ultrastructural features, but fixed viral strains generally cause severe neuronal degeneration that precludes the development, and thus the detection, of Negri bodies. Negri bodies also tend to occur more frequently in large neurons, such as the pyramidal neurons of the hippocampus, neurons of the medulla oblongata, and Purkinje cells of the cerebellum. Also, inclusions are frequently present in neurons not located in areas of inflammation. Therefore the preferred tissue for rabies examination by light microscopy and by florescent antibody technique for virus include hippocampus, cerebellum, medulla, and the trigeminal ganglion.

A spongiform lesion, indistinguishable qualitatively from the lesion characteristic for several of the spongiform encephalopathies, was described for the first time in 1984 by Charlton. This lesion was initially detected in experimental rabies in skunks and foxes, and later in the naturally occurring

## Pathologic Basis of Veterinary Disease, 4th Edition

---

disease in the skunk, fox, horse, cow, cat, and sheep. The lesion occurs in the neuropil of the gray matter, especially of the thalamus and cerebral cortex, initially as intracytoplasmic membrane-bound vacuoles in neuronal dendrites and less commonly in axons and astrocytes. The vacuoles enlarge, compress surrounding tissue, and ultimately rupture forming a tissue space. Although the mechanism responsible for the development of this lesion has not been determined, it is thought to result from an indirect effect of the rabies virus on neural tissue (possibly involving an alteration of neurotransmitter metabolism).

The clinical signs in domestic animals are similar with some differences between species. The clinical disease in the dog has been divided into three phases: prodromal, excitatory, and paralytic. In the prodromal phase, which lasts 2 to 3 days, the animal can have a subtle change in temperament. The term *furious rabies* refers to animals in which the excitatory phase is predominant, and dumb rabies refers to animals in which the excitatory phase is extremely short or absent and the disease progresses quickly to the paralytic phase. Cattle and carnivores generally have the furious form of rabies, and affected animals are restless and aggressive. Other somewhat unique signs of cattle with rabies include bellowing, general straining, tenesmus, and signs of sexual excitement followed by paralysis and death. Mules, sheep, and pigs usually have the excitatory form of rabies. Horses can have early signs that are atypical for a neurologic disease but terminally tend to have the excitatory form.

When conducting a necropsy on an animal suspected of having rabies, it is important to remember: (1) to provide additional protection (double-gloves, mask, eye protection, and proper ventilation) for the prosector above those used for routine postmortem examination and (2) to collect the appropriate CNS tissues (hippocampus, cerebellum, and medulla, and optionally the spinal cord) for examination by immunofluorescence and sometimes mouse inoculation. The remainder of the brain should be fixed by immersion in 10% neutral buffered formalin for histopathologic examination.

(**A** and **B**, Courtesy College of Veterinary Medicine, University of Illinois.)

### FUNGI AND ALGAE

Infection of the CNS by a variety of fungi and algae has been reported in domestic animals. Most reported cases are isolated occurrences and often represent opportunistic infection in immunocompromised individuals. Rare infections have involved genera such as *Aspergillus*, *Candida*, *Mucor*, dematiaceous fungi, and the blue-green algae *Prototheca*. These infections do not have a predilection for the nervous system. Of the systemic fungi, CNS infections have occurred with *Coccidioides immitis*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, and *Cryptococcus neoformans*, but only *Cryptococcus neoformans* has a particular affinity for the CNS and will be covered in a separate section later. These agents reach the CNS by leukocytic trafficking and hematogenous spread from primary sites of infection located in other areas (lung) of the body.

This group of pathogens usually elicits, as characterized by *Blastomyces dermatitidis*, a granulomatous to pyogranulomatous inflammatory response (Fig. 14-55). This response can be locally extensive or distinct granulomas can form in the CNS and meninges. Grossly, CNS lesions consist of moderately well demarcated expansile yellow-brown foci that displace and disrupt normal tissue (Fig. 14-56).

Microscopically the exudate consists of neutrophils, macrophages (epithelioid type), and multinucleated giant cells. The latter two cell types may contain organisms in their cytoplasm. *Blastomyces dermatitidis* organisms are broad-based budding spherical yeastlike organisms 8 to 25  $\mu\text{m}$  in diameter (Fig. 14-57).

The inflammatory response, including cells (granulomatous inflammatory cells) and cytokines, leads to the axonal, neuronal, and myelin disruption observed in these mycotic diseases.

890

891

CNS infections with *Coccidioides immitis* or *Histoplasma capsulatum* elicit an inflammatory response similar to that which occurs in *Blastomyces dermatitidis*. In coccidioidomycosis, the organisms are extracellular and/or intracellular spherules (20 to 30  $\mu\text{m}$  in diameter) containing endospores (<5  $\mu\text{m}$  in diameter), whereas in histoplasmosis, the organism principally is located intracellularly and is 5 to 6  $\mu\text{m}$  in diameter. The microscopic features of these fungi are compared in Fig. 14-57.

### *Cryptococcus neoformans*

Cryptococcosis, most commonly occurring in cats, dogs, and horses, is caused by *Cryptococcus neoformans*. This pathogen enters the leptomeninges and subarachnoid space by direct extension through the cribriform plate following a nasal or sinus infection or hematogenously by leukocytic trafficking usually from a pulmonary infection. Leptomeningeal inflammation can also extend along the roots of cranial nerves. *Cryptococcus neoformans* secretes a thick mucopolysaccharide capsule that protects the organism from host defenses. The accumulation of the organism and its mucopolysaccharide capsule gives the leptomeninges a cloudy to viscous appearance. The leukocytic response can vary from sparse to granulomatous. In some infected cats, *Cryptococcus neoformans* may be present in large numbers without an inflammatory response. It is unclear whether this absence of inflammation is due to suppression of the immune response by the organism or a defect in the cat's immune and/or inflammatory responses to the pathogen.

891

892

**Fig. 14-57 Morphology of fungi that may infect the central nervous system.** **A**, *Blastomyces dermatitidis*, 8 to 25  $\mu\text{m}$  in diameter, broad-based budding spherical yeastlike organisms, intracellular or extracellular location. H&E stain. **B**, *Cryptococcus neoformans*. In this illustration, the organism is surrounded by a mucinous capsule that is stained with Mayer's mucicarmine. The capsule varies in width, but can be so thick as to give the organism an overall diameter of 30  $\mu\text{m}$ . The organism without its capsule is 5 to 20  $\mu\text{m}$  in diameter. The capsule does not stain with H&E, thus causing the organism to appear to be surrounded by a clear halo (**Fig. 14-59, A**). The organisms are oval to spherical, but may be crescentic or cup shaped in routine mucicarmine and H&E stained sections. Dehydration that occurs during processing of the tissue to embed it in paraffin causes this shrinkage and distortion. Mayer's mucicarmine stain, aqueous wet mount. **C**, *Histoplasma capsulatum*, located intracellularly and is spherical to elongated, 5 to 6  $\mu\text{m}$  in diameter. H&E stain. **D**, *Coccidioides immitis*, spherules (20 to 30  $\mu\text{m}$  in diameter) containing endospores (<5  $\mu\text{m}$  in diameter), can be intracellular or extracellular. H&E stain. (**A through D**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Two virulence factors have been documented. First, a thick mucopolysaccharide capsule protects the organism from host defenses. Second, virulent organisms possess a biochemical pathway that can use catecholamines and that consists of a specific transport pathway and the enzyme phenoloxidase with production of a melanin or melanin-like compound through a series of oxidation-reduction reactions. This pathway can help protect the organism from oxidative damage in the brain. Both virulence factors are important for survival of the organism in the host. In addition, CSF lacks alternative pathway complement components that bind to the organism's carbohydrate capsule and facilitate phagocytosis and killing by neutrophils.

**Fig. 14-58 Cryptococcosis, thalamus, cerebellum, and mesencephalon, transverse sections, cat.** Note the “cavitation” lesions caused by *Cryptococcus neoformans* (arrows). Although the lesions look like cavities, they are filled with organisms, and the faint gray appearance is caused by the mucinous capsules of numerous cryptococci. *Cryptococcus neoformans* usually induces a granulomatous inflammation in most domestic animals, but in some animals, especially the cat, inflammation is minimal or absent. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Grossly in CNS tissue and the leptomeninges, multiple small “cysts” with a viscous, gelatinous appearance can be seen (Fig. 14-58). Microscopically, leptomeningeal lesions have a loosely organized, lacy appearance with often myriad cryptococcal organisms and little or no inflammation. The leptomeningeal reaction can extend along the roots of cranial nerves. Spread of the CNS infection results in ventriculitis and choroiditis. In CNS tissue, in addition to the presence of the organism and its capsule, the response can vary from being sparse to a granulomatous inflammation.

The leukocytic response consists of neutrophils, eosinophils, macrophages, giant cells, and small mononuclear cells, depending on the immune status of the host. Animals with normal immune responses usually clear the infection from nasal cavities, sinuses, and the pulmonary system before it spreads systemically. Resistance to infection is provided by cell-mediated immunity. Immunosuppression of cell-mediated immunity caused by FIV and FeLV in cats and by *Ehrlichia canis* or long-term glucocorticoid therapy in dogs appear to increase susceptibility to cryptococcosis.

The yeast is spherical (2 to 10  $\mu\text{m}$  in diameter), crescentic, or “cup shaped,” usually surrounded by a thick nonstaining (H&E stain) capsule (1 to 30  $\mu\text{m}$  in diameter), and reproduces by narrow-based buds (Fig. 14-59, A). Special stains, such as periodic acid–Schiff and Gomori's methenamine silver, demonstrate the organisms readily, and the capsule can be stained with mucicarmine and alcian blue (Fig. 14-59, B).

892

893

**Fig. 14-59 Leptomeningeal cryptococcosis. A,** The thick unstained mucinous capsule surrounding the organism results in the formation of a clear space (halo) in H&E stained sections (arrow). This feature is useful in identifying the organism in cytologic preparations and tissue sections. Also see Fig. 14-57, B. H&E stain. **B,** The mucinous capsule surrounding the organism also stains with mucicarmine, providing a simple method to identify the organism (arrow). Mayer's mucicarmine stain. ## Pathologic Basis of Veterinary Disease, 4th Edition

Clinically, cryptococcosis with CNS infection occurs in cats, dogs, horses, and cattle. The character of neurologic signs varies with the location of the lesions but can include depression, ataxia, seizures, paresis, and blindness.

14.1.2.2.3.2

### Opportunistic Fungi

Opportunistic fungi—including those fungi in the zygomycetes group, such as *Absidia corymbifera*, *Rhizomucor pusillus*, and *Rhizopus arrhizus*, and those fungi in the genus *Aspergillus*, such as *Aspergillus niger*—can invade blood vessels (angiotropic) and cause vascular thrombosis and infarcts in the CNS (Fig. 14-60). It must be noted that the term *opportunistic* implies that some form of tissue damage precedes fungal invasion. As an example, necrotizing enterolitis caused by *Salmonella* spp. in the horse can provide an “open” vascular bed in the lamina propria of the intestinal mucosa that may be invaded by such fungi. Affected animals are often immunocompromised.

14.1.2.2.4

### PROTOZOA

14.1.2.2.4.1

### Equine Protozoal Encephalomyelitis (Sarcocystosis)

Equine protozoal encephalomyelitis is a disease in horses caused by *Sarcocystis neurona*. The organism enters the body through ingestion of sporocysts, but how the parasite enters the CNS is unclear. Experimental studies suggest that ingested sporocysts multiply in visceral tissue, perhaps the intestine, and then are transported to the CNS probably via leukocytic trafficking. In the CNS, the typical sequence of events in the pathogenesis of the characteristic lesion is thought to be: (1) leukocytic trafficking with focal parasitic activation and replication, (2) marked inflammation, (3) edema, and (4) pronounced tissue destruction affecting both white and gray matter.

**Fig. 14-60 Opportunistic angioinvasive fungi.** Fungi such as *Absidia corymbifera*, *Rhizomucor pusillus*, and *Rhizopus arrhizus* and fungi in the genus *Aspergillus*, such as *Aspergillus niger*, can invade blood vessels (angiotropic) and cause vascular necrosis and infarcts in the central nervous system. Note the vasculitis, hemorrhage, and disruption of the vessel and the fungal hyphae in the lumen (arrow). H&E stain. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Gross lesions can occur throughout the neuraxis but are more common in the spinal cord, particularly the cervical and lumbar intumescences, than in the brain. In the brain, lesions are most commonly seen in the brain stem. When gross lesions are present, they consist of discolored necrotic foci, often with hemorrhage of varied sizes (Fig. 14-61).

Microscopic lesions occur in both the white and gray matter and include necrosis, hemorrhage, and accumulations of lymphocytes, macrophages, neutrophils, eosinophils, and a few multinucleated giant cells in perivascular areas and the neuropil, or less commonly, the leptomeninges and the axonal swelling. Gemistocytic astrocytosis can be prominent. In lesions, *Sarcocystis neurona* is small and crescent-shaped to round, has a well-defined nucleus, and is often arranged in aggregates or rosettes (Fig. 14-62). Organisms can be difficult to detect but occur intracellularly in neurons, giant cells, neutrophils, or macrophages or occur extracellularly in cysts within the neuropil. *Sarcocystis neurona* is not typically seen in vascular endothelial cells, a common site for other members of this genus.

893

894

B, Lumbar spinal cord, transverse section. Myelitis due to *Sarcocystis neurona* infection. Prominent focal hemorrhage and necrosis are present in the right lateral funiculus and in the right and left ventral funiculi. (A, Courtesy College of Veterinary Medicine, University of Illinois. B, Courtesy Dr. R. Storts, College of Veterinary Medicine, Texas A&M University.)**

Fig. 14-62 ***Sarcocystis neurona*, brain, horse.** *Sarcocystis neurona* is a small, crescent-shaped to round protozoal organism found in neurons, endothelial cells, and microglial cells. They can be arranged in nonencysted aggregates (arrow) or rosettes intracellularly and in central nervous system tissue often with a mixed leukocytic cellular inflammatory response of varied severity. Organisms can be difficult to detect in histologic sections. H&E stain. (Courtesy Dr. J. Simon, College of Veterinary Medicine, University of Illinois.)

*Sarcocystis neurona* can be propagated in tissue culture where it develops in the host cell cytoplasm. It divides by endopolygony, with development of schizonts containing merozoites arranged in rosettes around a prominent residual body. The schizont stage of the organism differs from those of the genera *Toxoplasma*, *Isospora*, *Eimeria*, *Besnoitia*, *Hammondia*, and *Neospora* because the merozoites lack rhoptries but resemble the schizont stage of other genera such as *Sarcocystis* spp. and *Frenkelia*. It is proposed that an opossum coccidian, *Sarcocystis falcatula*, and *Sarcocystis neurona* are synonymous. Studies have suggested that the opossum represents the definitive host and avian species the intermediate host, providing a reservoir for infection of the horse.

*Sarcocystis* spp. infection in nonequine species involves organisms similar to *Sarcocystis neurona*. Such organisms have been associated with encephalomyelitis in cattle, sheep, and dogs as well as raccoons, but such infections are sporadic. Lesions and organisms have additionally been seen in the CNS of infected bovine fetuses.

Clinical infection typically occurs in young adult horses, and signs are dependent on the area of the CNS parasitized. Signs can include depression, behavioral changes, seizures, gait abnormalities, ataxia, facial nerve paralysis, head tilt, paralysis of the tongue, urinary incontinence, dysphagia, atrophy of masseter and/or temporal muscles, and atrophy of the quadriceps and/or gluteal muscles.

### Neosporosis

Neosporosis, a naturally occurring or experimental disease caused by *Neospora caninum* or a Neospora-like coccidian, has been recognized in a variety of animals, including the dog, cat, cattle, sheep, and horse (*Neospora hughesi*) as well as laboratory rodents. First described in 1988 as a multisystemic infection in the dog, the organism has an affinity for the nervous system. The dog has recently been identified as the definitive host for the organism, but other hosts may exist. Some of the features of the organism similar to those of *Toxoplasma gondii*, include division of tachyzoites by endodyogeny and having both proliferative (tachyzoites) and tissue cyst phases. However, *Neospora caninum* does not develop within a parasitophorous vacuole of a host cell, as does *Toxoplasma gondii*. This latter feature is evident only with the use of transmission electron microscopy.

Although there are morphologic differences between the organisms (*Neospora caninum* has a thicker cyst wall), differentiation by light microscopy is unreliable, and electron microscopic examination or immunohistochemistry is required. Apart from transplacental transmission proposed for a variety of species, the mechanism of infection is unknown. *Neospora caninum* can infect a variety of cell types, but outside of the CNS it appears to have an affinity for cells of the monocyte-macrophage system. The most likely method of spread to the CNS is via leukocytic trafficking.

In the CNS, neurons and ependymal cells, mononuclear cells in the CSF, and cells of blood vessels including endothelium, intimal connective tissue, and tunica media smooth muscle cells can harbor organisms. Organisms have also been detected in spinal nerves. In all animals studied to date, the cyst form of *Neospora caninum* has been seen only in the CNS, whereas tachyzoites have been found in a variety of other tissue. Overall the morphologic pattern and character of lesions caused by *Neospora* spp. in the CNS are most consistent with endothelial tropism, vascular swelling and injury, tissue ischemia, and multifocal infarction.

Neurologic disease can be divided into two categories; that occurring during postnatal life and that associated with midterm to late-term abortions, the latter a notable problem in dairy cattle. Postnatal syndromes have been observed mainly in young and adult dogs, but horses are also affected. In young dogs, clinical signs are due to an ascending polyradiculoneuritis and polymyositis. In adult dogs, clinical signs are more referable to CNS lesions complicated by polymyositis, myocarditis, and dermatitis.

In horses the pathogen causing neosporosis is *Neospora hughesi*. Clinical signs resemble those of protozoal myeloencephalitis caused by *Sarcocystis neurona*. Lesions in horses include meningoencephalomyelitis, variable vasculitis and necrosis with microgliosis, and perivascular cuffing by macrophages, multinucleated giant cells, lymphocytes, plasma cells, or neutrophils, most commonly in the gray and white matter of the spinal cord but also in the pons and medulla.

Gross lesions can involve the white and/or gray matter. Peracute gross lesions may include foci of hemorrhage and necrosis distributed in a vascular pattern. Acute lesions have the same pattern of distribution but are, on cut surface, granular in texture and yellow-brown to gray. In some cases the periventricular white matter may be more affected. Chronic lesions have larger areas of granular yellow-brown to gray discoloration, which often makes white matter indistinguishable from gray matter. Microscopically the lesions and their temporal occurrence are similar to those described for *Toxoplasma gondii* including brain lesions that occur in aborted animals. *Neospora caninum* or Neospora-like organisms in lesions can be identified in tissue sections by H&E stain and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

immunohistochemical staining methods. Clinical signs are similar to those described for encephalitides induced by *Toxoplasma gondii*.

14.1.2.2.4.3

### Toxoplasmosis

Toxoplasmosis is a disease in cats and other mammalian species caused by the obligate intracellular protozoan, *Toxoplasma gondii*. Domestic, feral, and wild cats are the definitive hosts of *Toxoplasma gondii*. Cats acquire *Toxoplasma gondii* by ingesting infective cysts, oocysts, or tachyzoites when eating infected prey, such as rodents or birds. Ingestion of one of these stages initiates the intrainestinal life cycle, which occurs only in members of the cat family. *Toxoplasma gondii* replicates and multiplies within epithelial cells of the small intestine and produces oocysts. Oocysts are released into the feces in large numbers for 2 to 3 weeks following initial ingestion of cysts, oocysts, or tachyzoites. When oocysts sporulate, usually within 5 days after passage in the feces, they become infectious for intermediate hosts. Sporulated oocysts are highly resistant and can survive in moist shaded soil or sand for months. Cats are unique in the biology of the organism, serving as both definitive (intrainestinal life cycle) and intermediate (extraintestinal life cycle) hosts.

*Toxoplasma gondii* can infect a wide variety of animals as intermediate hosts (extraintestinal life cycle) including fish, amphibians, reptiles, birds, human beings, and many other mammals. New World monkeys and Australian marsupials are the most susceptible, whereas Old World monkeys, rats, cattle, and horses seem highly resistant.

*Toxoplasma gondii* can also parasitize a wide variety of cell types in the intermediate host and can cause lesions in such tissues as the lungs, lymphoid system, liver, heart, skeletal muscle, pancreas, intestine, eyes, and nervous system. Following ingestion, bradyzoites from tissue cysts or sporozoites from oocysts enter intestinal epithelia and multiply. Evidence suggests active penetration of plasma membranes by organism-secreted lytic products, allowing a portal of entry rather than by uptake via phagocytosis. *Toxoplasma gondii* can then spread locally, free in lymph or intracellularly in lymphocytes, macrophages, or granulocytes to Peyer's patches and regional lymph nodes. Intracellularly, organisms multiply as tachyzoites within a parasitophorous vacuole by repeated cycles of endodyogeny during the early acute stages of infection. Dissemination to distant organs is via lymph and blood, either as free organisms or intracellularly in lymphocytes, macrophages, or granulocytes via leukocytic trafficking.

With chronicity and an increasing antibody response by the host, tachyzoites of *Toxoplasma gondii* transform into slow-growing bradyzoites that replicate in cysts within muscle. Infection of the CNS occurs hematogenously; neurons and astrocytes are the eventual target cells. The typical sequence of events in the pathogenesis of the characteristic lesion is similar to that in *Sarcocystis neurona* infection. In utero infections in animals and human beings can result in CNS infection. In fetal brains, foci of necrosis are most common in the brain stem and induce the formation of microglial nodules. Additionally, foci of necrosis and mineralization occur in the cerebrocortical white matter and are caused by fetal hypoxia and ischemia resulting from severe placentitis, fetal myocardial damage, or initiation of a systemic inflammatory reaction in the fetus. In older more mature individuals, *Toxoplasma gondii* infections have been associated with immunosuppression, such as occurs in concurrent CDV infection and toxoplasmosis. In some cases this could represent activation of latent inactive *Toxoplasma gondii* cysts [bradyzoites] in neural tissues.

Immune-mediated mechanisms have been proposed to explain the vascular injury (type III hypersensitivity) and cellular or tissue necrosis (type IV hypersensitivity). Lysis of infected cells by

## Pathologic Basis of Veterinary Disease, 4th Edition

primed cytotoxic, CD8<sup>+</sup> T lymphocytes also could potentially contribute to the tissue damage through the production of cytokines, such as INF- $\gamma$ , which can activate microglia and astrocytes to inhibit parasite replication and induce cytotoxic T lymphocytes to kill infected cells. This exuberant inflammatory response and the cytokine cascade that ensues to kill the organism also causes severe damage to cells in the area of inflammation, especially axons and neurons. Intracellular growth of tachyzoites also has been advanced as a cause of cellular necrosis. The organism does not produce a cytotoxin.

895

896

The blood-brain barrier of the CNS is breached when free organisms or those located intracellularly (leukocytic trafficking) infect endothelial cells of the CNS vasculature, especially capillaries. Gross lesions can involve any area of the CNS without predilection for gray or white matter, may also involve nerve rootlets, and may initially include foci of hemorrhage and necrosis and, later, by granular, yellow-brown to gray foci. Peracute lesions initially include endothelial cell swelling due to infection by tachyzoites and vasculitis with hemorrhagic infarcts followed by vasogenic edema. If the edema is of sufficient severity to cause increased brain volume, the edema can lead to brain displacement and herniation.

Early microscopic lesions include infection of and proliferation within endothelial cells by *Toxoplasma gondii* tachyzoites. Endothelial injury results in endothelial cell swelling, endothelial cell degeneration, hemorrhage, capillary occlusion, ischemic necrosis, and edema of adjacent tissue. Subsequently, tachyzoites invade the CNS, inducing a prominent acute inflammatory response leading to necrosis and hemorrhage often striking in severity. With time, the inflammatory response consists of perivascular cuffing of blood vessels within the CNS and leptomeninges by lymphocytes and macrophages. CNS responses to injury consist of microgliosis and astrogliosis; however, these responses are often insufficient to replace the loss of tissue in the cerebral hemispheres, resulting in dilatation of the lateral ventricles (hydrocephalus ex vacuo) and the formation of persistent cysts in the tissue. With chronicity and increasing inflammatory and immunologic responses by the host, tachyzoites change to slow-growing bradyzoites that replicate in and form tissue cysts. Organisms in lesions can often be identified with an H&E stain, but immunohistochemistry facilitates their detection and identification. As the infection is systemic, lesions can occur in several other tissues.

Occasionally, cysts (bradyzoites) can be observed in “normal” CNS tissue without an inflammatory or tissue lesion. These cysts are likely the result of a previous infection with *Toxoplasma gondii* that was successfully resolved. Experimental studies have confirmed that administration of corticosteroids, and hence immunosuppression, increases susceptibility or exacerbates the infection with *Toxoplasma gondii* or both or may contribute to the reactivation of tissue cysts.

Clinical signs can vary depending on the age of the animal, species infected, and areas of the CNS involved and may include depression, weakness, incoordination, tremors, circling, paresis, and blindness.

14.1.2.2.6

### PARASITES

As a general concept, lesions resulting from parasitic infestation of the CNS vary in degree of severity and distribution depending on the parasite and the host response to infection. Gross lesions of hemorrhage and malacia in parasite migratory tracts or space-occupying cysts occur with the various parasitic stages. Microscopically, there is necrosis, hemorrhage, and a leukocytic response, typically with a significant infiltrate of eosinophils. The extent of the host response is often dictated by the degree of trauma and disruption created by the parasite and the level of sensitivity of the host for parasite antigens. This section is not intended to be an extensive review of veterinary parasitology but will cover those parasites most commonly seen in veterinary practice.

14.1.2.2.6.1

### Insect Larvae

Among the most common larvae are those of *Oestrus ovis* and *Hypoderma bovis*. The larvae of *Oestrus ovis* develop in the nasal cavity of sheep but can penetrate into the cranial vault through the ethmoid bone. Larvae of *Hypoderma bovis* can enter the spinal canal during their migration in the subcutis from the hoof to the dorsal midline in cattle and rarely as an aberrant parasite in the brain of horses. Damage in the CNS due to *Hypoderma bovis* in cattle is typically the result of inflammation directed at the degenerating parasites following anthelmintic treatment. Larvae of *Cuterebra* spp., usually a parasite of rabbits and rodents, can invade the CNS of dogs and cats (see Feline Ischemic Encephalopathy).

14.1.2.2.6.2

### Cestodes

*Coenurus cerebralis*, the larval form of the dog tapeworm *Multiceps multiceps*, most commonly infests sheep and occasionally other ruminants. The larval forms presumably reach the CNS hematogenously and then cause damage during migration and encystation, forming space-occupying lesions. Another parasite for which human beings are the definitive host is *Taenia solium*, with pigs being the intermediate host. The larval stage, *Cysticercus cellulosae*, generally develops in muscle of the pig but can also occur in the meninges and brain, resulting in a disease called “cysticercosis.” Involvement of the CNS has been termed “neurocysticercosis.”

896

Initially, viable cysticerci become “trapped” within capillaries of the CNS, but they do not apparently elicit an inflammatory response. At some point, the host responds immunologically and the cyst becomes denser, collapses inwardly, and disintegrates to eventually become calcified debris in a focus of inflammation. The inflammatory response has humoral and cellular components. Antibodies of the IgG family are directed against the cyst; however, cysts are likely killed by mediators released from eosinophils, which are attracted to the site by mediators released from lymphoid cells in the inflammatory exudate. For undetermined reasons, in “susceptible” animals viable cysts can become established and grow slowly for years. Viable cysticerci can cause asymptomatic infection by actively evading and suppressing the immune response of the host. These cysts cause vasogenic edema and increased intracranial pressure related to behavior as “space-occupying” masses.

897

Gross lesions are usually seen in the cerebral hemispheres, commonly at the interface of gray and white matter in a hematogenous pattern. Cysts can also be found in the cerebellum, medulla, ventricles, subarachnoid space, and the spinal cord. There are usually no gross changes in the CNS surrounding the cysts. Cysts are round to oval and of varied sizes and number, many of which can be large and visible up to centimeters in diameter. They have a translucent cyst wall and contain a thick, clear fluid.

## Pathologic Basis of Veterinary Disease, 4th Edition

Within the fluid is a scolex, visible as a small 2- to 3-mm nodule. Microscopically, there is little or no inflammation or tissue injury surrounding the cysts, except for compression and edema.

14.1.2.2.6.3

### Nematodes (Cerebrospinal Nematodiasis)

Aberrant migration of larval stages of nematode parasites into and through the CNS is called cerebrospinal nematodiasis. They gain access to the CNS hematogenously and actively enter the CNS by crossing the blood vessel wall through their locomotive processes. Nematodes cause damage in the cerebromedullary area of the brain and/or spinal cord either from aberrant migration in the definitive host or migration in an aberrant host (Table 14-5; Fig. 14-63). Larval stages of *Strongylus* spp. and *Baylisascaris procyonis*, for example, are typically involved, the exception being *Dirofilaria immitis*, where the adult parasite is found. Greater CNS damage is often created by the migration of the parasites in an aberrant host.

Macroscopic lesions of nematode larval migration often appear as linear or serpentine tracts of necrosis and/or hemorrhage in the tissue. Migration results in endothelial injury, vasculitis, and thrombosis, which may result in vascular occlusion and infarction. Larvae can often be found in histologic sections, and they induce a mononuclear cell inflammatory exudate, including abundant eosinophils (Fig. 14-64).

Table 14-5 Nematodes Causing Central Nervous System Disease in Domestic Animals

Parasite	Normal Host	Aberrant Host

<i>Setaria digitata</i>	Cattle	Sheep, goat, horse
ABERRANT NEMATODE MIGRATION IN NORMAL HOST		
<i>Angiostrongylus vasorum</i>	Dog (coyote)	
<i>Dirofilaria immitis</i>	Dog (cat)	
<i>Stephanurus dentatus</i>	Pig	
<i>Strongylus</i> spp.	Horse	

**Fig. 14-63 Cerebrospinal nematodiasis, brain, cerebellum, and medulla at the level of the pons, horse. *Strongylus vulgaris* migration.** Several small foci of hemorrhage and necrosis in the cerebellar white matter are sites of larval migration (*arrows*). (Courtesy Dr. R. Storts, College of Veterinary Medicine, Texas A&M University.)

*Halicephalobus (Micronema) deletrix* is a free-living rhabditiform nematode that can infest the nasal cavity, CNS, and kidneys of the horse. The life cycle, pathogenesis, and route of infection of *Halicephalobus deletrix* are poorly understood. It has been proposed that the CNS is infected hematogenously in a manner similar to that described for cerebrospinal nematodiasis and that larvae penetrate skin and mucous membranes in recumbent horses with subsequent invasion of sinuses and/or blood vessels. In the CNS, microscopic lesions are prominently associated with blood vessels along which the parasite apparently migrates.

### PRIONS

14.1.2.2.7.1

### Transmissible Spongiform Encephalopathies

Ovine spongiform encephalopathy (scrapie), bovine spongiform encephalopathy (BSE), and human spongiform encephalopathies are classified within a group of diseases called transmissible spongiform encephalopathies (TSEs). [Table 14-6](#) lists the known TSEs in animals and human beings. These diseases are caused by proteinaceous infectious particles (prions) that: (1) are composed of an abnormal

## Pathologic Basis of Veterinary Disease, 4th Edition

---

isoform of a normal cellular protein, the prion protein (PrP<sup>c</sup> [a 27- to 30-kilodalton polypeptide]), designated PrP<sup>Sc</sup> and (2) resist inactivation by procedures that degrade nucleic acids and proteins (i.e., heat, ultraviolet irradiation, and strong enzymes). PrP<sup>c</sup> is expressed throughout the body and is the product of a highly conserved gene found in organisms as diverse as fruit flies and human beings. The “Sc” superscript is derived from the word “scrapie” because scrapie is the prototype prion disease.

**Fig. 14-64 Cerebrospinal nematodiasis, central nervous system (CNS), horse.** Migration of *Strongylus vulgaris* larvae (arrow) in the CNS elicits a perivascular lymphomonocytic inflammatory response mixed with eosinophils (arrowhead) and results in direct injury to blood vessels, axons, and dendrites. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

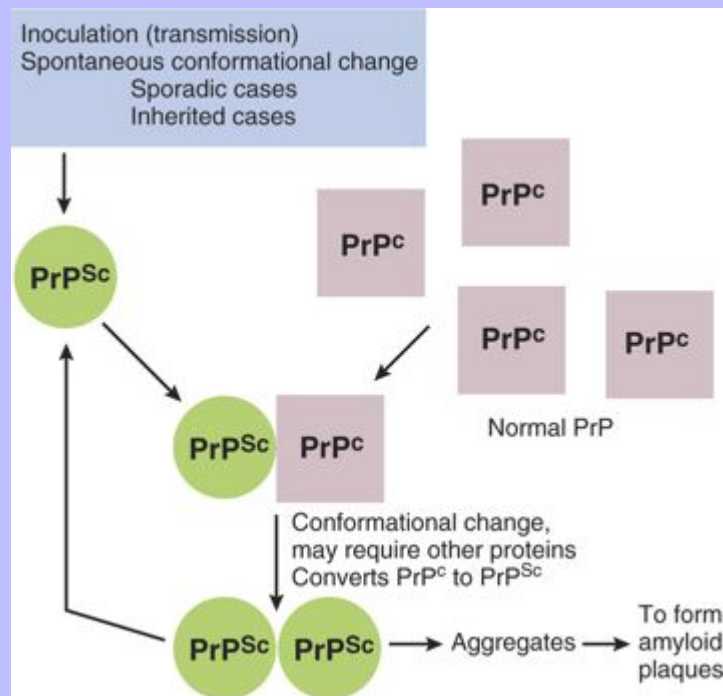

Table 14-6 Transmissible Spongiform Encephalopathies (i.e., Prion Diseases)

Disease	Natural Host(s)	Prion	Pathogenic PrP Isoform
<b>ANIMALS</b>			
Ovine spongiform encephalopathy (scrapie)	Sheep, goats	Scrapie prion	OvPrP <sup>Sc</sup>
Bovine spongiform encephalopathy (BSE)	Cows	BSE prion	BoPrP <sup>Sc</sup>
Feline spongiform encephalopathy (FSE)	Cats	FSE prion	FePrP <sup>Sc</sup>
Chronic wasting disease (CWD)	Mule deer, elk, black tailed deer, white tailed deer	CWD prion	MdePrP <sup>Sc</sup>
Transmissible mink encephalopathy (TME)		TME prion	MkPrP <sup>Sc</sup>
Exotic ungulate encephalopathy (EUE)	Nyala, greater kudu, oryx	EUE prion	UngPrP <sup>Sc</sup>
<b>HUMAN BEINGS</b>			
Kuru	Human beings	Kuru prion	HuPrP <sup>Sc</sup>
Creutzfeldt-Jakob disease (CJD)	Human beings	CJD prion	HuPrP <sup>Sc</sup>
Variant Creutzfeldt-Jakob disease (VCJD)	Human beings	VCJD prion	HuPrP <sup>Sc</sup>
Gerstmann-Sträussler-Scheinker syndrome (GSS)	Human beings	GSS prion	HuPrP <sup>Sc</sup>
Fatal familial insomnia (FFI)	Human beings	FFI prion	HuPrP <sup>Sc</sup>

Although the mechanism by which PrP<sup>Sc</sup> forms has not been completely explained, a posttranslational modification of PrP<sup>C</sup> has been proposed (Fig. 14-65). This mechanism proposes that PrP<sup>Sc</sup> acts as a template on which PrP<sup>C</sup> undergoes a conformational change (is refolded) by a process facilitated by another protein (referred as protein X), whereby the  $\alpha$ -helical content of PrP<sup>C</sup> diminishes and the amount of  $\beta$ -sheet increases, resulting in the formation of PrP<sup>Sc</sup>. The features of a specific PrP<sup>Sc</sup> is determined by the animal in which it is formed. When PrP<sup>Sc</sup> of one species is inoculated into a different species, the recipient is less readily infected and generally has a prolonged incubation period. This resistance to infection is referred to as the “species barrier.” A review of prion biology and diseases can be found in Prusiner (2004) in the suggested readings. Dr. Prusiner was awarded the Nobel Prize in Medicine in 1997 for his work on prion diseases.

898

Fig. 14-65 **Prion protein.** In prion diseases (spongiform encephalopathies), PrP ( $PrP^C$ ), a normal neuronal protein, is converted to an abnormal  $\beta$ -pleated sheet isoform ( $PrP^{Sc}$ ) through the interaction of  $PrP^{Sc}$  with  $PrP^C$ . (Modified from Cotran RS, Kumar V, Collins T, Robbins SL: Robbins pathologic basis of disease, ed 6, Philadelphia, 1999, Saunders.)

Spongiform encephalopathies occur through horizontal transmission (scrapie-infected sheep offal\* fed to cows [BSE] has been proposed) and through an inherited mutation of the normal human prion gene (parent to child), resulting in the spontaneous formation of PrP<sup>Sc</sup>. In animals the primary route of infection appears to be through horizontal transmission. It has been proposed that prions ingested in infective feedstuffs enter the body through the intestine. The role of the rendering process in the pathogenesis of prion infectivity is also unclear. Prions are thought to cross the intestinal wall at Peyer's patches and are phagocytosed and transported to other lymph nodes by leukocytic trafficking. Prions replicate in lymphocytes and macrophages of the lymphoid system. Because these tissues are innervated, prions have been proposed to be transported by retrograde axonal transport to the brain; however, hematogenous spread via leukocytic trafficking may also be involved. In this example, scrapie infective ovine prions (OvPrP<sup>Sc</sup>) accumulate in neurons and somehow result in the conversion of normal bovine prion proteins (BoPrP<sup>C</sup>) in neurons to the disease-causing form, BoPrP<sup>Sc</sup> through a process in which a portion of the  $\alpha$ -helical and coil structure of PrP<sup>C</sup> is refolded into  $\beta$ -sheets (PrP<sup>Sc</sup>).

## Pathologic Basis of Veterinary Disease, 4th Edition

---

When neurons accumulate sufficient PrP<sup>Sc</sup> to alter the normal function of neurons (it can take years), neurologic signs are observed.

Prion diseases are fatal. The adaptive immune system does not recognize prions as foreign; therefore no immunologic protection develops. How the accumulation of PrP<sup>Sc</sup> causes neurodegeneration and neuron loss in prion diseases is not clear; however, astrocyte and microglial cell activation and apoptosis appear to be likely components of the pathway leading to neuronal injury.

No gross lesions of the nervous system are detectable in animals with spongiform encephalopathies. Microscopic lesions in scrapie-infected sheep and goats are limited to the CNS and are most commonly present in the diencephalon, brain stem, and cerebellum (cortex and deep nuclei), with variable lesions in the corpus striatum and spinal cord. Except for some minor changes, the cerebral cortex is essentially unaffected.

The type of neuronal degeneration can vary and commonly is characterized by shrinkage with increased basophilia and cytoplasmic vacuolation (Fig. 14-66, A), although other changes such as central chromatolysis and ischemic cell change variably occur. Astrocytosis in affected areas of the brain, including the cerebellar cortex, can be severe (Fig. 14-66, B). There has been speculation whether the astrocytic reaction is a primary or a secondary response. An abnormal protein (prion amyloid protein) first accumulates in astroglial cells in the brain during scrapie infection, which could mean that this cell is the primary site of replication. The spongiform change tends to affect the gray matter, and greater severity of this lesion has been associated with long incubation periods. The lesion in the gray matter is the result of dilation of neuronal processes, but vacuolation of neuronal and astroglial perikarya, swelling of astrocytic processes, dilation of the periaxonal space, and splitting of myelin sheaths have also been reported. Finally, the disease is not accompanied by any notable inflammation within the CNS.

### 14.1.2.2.7.1.1

#### Ovine spongiform encephalopathy (scrapie)

Scrapie is best known as a degenerative disease that affects the CNS of sheep and was first recognized in Great Britain and other countries of Western Europe more than 250 years ago. The disease, which is currently reported throughout the world except for Australia and New Zealand, also occurs naturally in the domestic goat. The name is derived from the characteristic clinical signs of pruritus, which often results in loss of wool in sheep. The disease progresses inexorably with early signs of subtle change in behavior or temperament followed by scratching and rubbing against fixed objects because of the pruritus. Additional signs include incoordination, weight loss (despite retention of appetite), biting of the feet and limbs, lip smacking, gait abnormalities, trembling (when suddenly stressed), recumbency, and eventually death after 1 to 6 months or longer.

900

**Fig. 14-66 Spongiform encephalopathy (scrapie), brain, motor neurons, sheep. A, Neuronal cell bodies contain one or more discrete and/or coalescing clear vacuoles. There are no inflammatory cells in this disease. Similar spongiosis is evident in the neuropil. H&E stain. B, Scrapie, experimental, brain, cerebellum, mouse. The cerebellar granule cells are at the top of the figure. There is notable hypertrophy and proliferation (astrocytosis) of astrocytes and their fibers (astrogliosis) (*black branching fibers*). Some of the processes (running diagonally across the illustration) end, as is normal for astrocytes on the walls of capillaries. Cajal's gold sublimate stain for astrocytes. (A, Courtesy Dr. D. Gould, College of Veterinary Medicine; and Biomedical Sciences, Colorado State University; and Dr. M. McAllister, College of Veterinary Medicine, University of Illinois. B, Courtesy Dr. W.J. Hadlow.)**

Much of our current understanding of the pathogenesis of the natural infection of scrapie in Suffolk sheep has been advanced by Dr. William Hadlow and co-workers. It should be noted that Dr. Hadlow is a veterinary pathologist and diplomate of the American College of Veterinary Pathologists, who first recognized and reported the similarity between scrapie and kuru of human beings. This important contribution led to the current understanding of the TSEs and a Nobel Prize for the medical scientist (Dr. D. Gajdusek), who originally investigated kuru in the South Pacific.

\* Viscera and trimmings of butchered animals considered inedible by human beings.

### 14.1.2.2.7.1.2

#### Bovine spongiform encephalopathy

BSE (mad cow disease) was originally identified in the United Kingdom in 1986 but likely existed there as early as April 1985. Through the end of 2003, more than 183,000 cows from more than 35,000 herds were reported with BSE. With regard to the origins of BSE, epidemiologic evidence strongly suggests that this disease was caused initially (during the early 1980s) by the feeding of rations containing meat and bone meal supplements that were contaminated with the scrapie agent.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Countries that have reported cases of BSE or are considered to have a substantial risk to have animals with BSE include: Albania, Austria, Belgium, Bosnia-Herzegovina, Bulgaria, Canada (confirmed May 2003), Croatia, Czech Republic, Denmark, Federal Republic of Yugoslavia, Finland, France, Germany, Greece, Hungary, Ireland, Israel, Italy, Liechtenstein, Luxembourg, Former Yugoslavia Republic of Macedonia, The Netherlands, Norway, Oman, Poland, Portugal, Romania, Slovak Republic, Slovenia, Spain, Sweden, Switzerland, Japan, and United Kingdom (Great Britain including Northern Ireland and the Falkland Islands).

In December 2003, BSE was confirmed in a single dairy cow from a herd in Washington state. This cow was apparently imported into the United States 2 to 3 years earlier from a farm in northern Alberta, Canada, which was the source of the positive BSE case in Canada confirmed in May 2003. In 2004, additional cases of BSE likely linked to a common source were reported in Washington state, Oregon, and Canada, and in June 2005 a cow tested positive for BSE in Texas.

Signs that accompany BSE include changes in behavior, such as nervousness or aggressiveness, abnormal posture, abnormal gait, incoordination, difficulty in rising, decreased milk production, and loss of body weight despite continued appetite. Clinically affected cattle deteriorate until they either die or require euthanasia. This clinical period usually ranges from 2 weeks to 6 months. All cases of the disease in cattle have occurred in adult animals, with an age range of 3 to 11 years, but most animals have clinical signs develop between 3 and 5 years of age.

The National Veterinary Services Laboratory (APHIS—Animal and Plant Health Inspection Service) of the United States Department of Agriculture has developed and implemented through local and regional veterinary diagnostic laboratories procedures for sampling, preparing, and submitting brains for BSE analysis. Space limitations prevent describing these procedures. They can be obtained through APHIS or a diagnostic laboratory. Dead or sick animals that display neurologic signs and are suspected of being potential BSE candidates are tested using immunohistochemical analysis, Western blot analysis, or enzyme-linked immunosorbent assay to identify PrP<sup>Sc</sup> in brain tissue. Genetically valuable animals that may be exported or have their embryos or DNA saved for future use and are from TSE risk groups can be tested for PrP<sup>Sc</sup>. Immunohistochemical analysis for PrP<sup>Sc</sup> of samples obtained (i.e., under anesthesia) from biopsies of tonsil and lymph follicles of the third eyelid from at-risk groups show promise as diagnostic tools.

900

901

### 14.1.2.3 DEGENERATIVE DISEASES

#### 14.1.2.3.1 METABOLIC

##### 14.1.2.3.1.1 Aging-Related Degenerative Myelopathy (German Shepherd Myelopathy)

A degenerative myelopathy is most commonly seen in the German shepherd, but a similar condition has been described in other large canine breeds (Belgium shepherd, Old English sheepdog, Rhodesian ridgeback, Weimaraner, great pyrenees). Based on its prevalence in German shepherds, it has been suggested that there is a genetic “aging” predisposition in this breed. Altered suppressor lymphocyte activity has been noted in affected dogs, but the relevance to the CNS disease is unknown. Some investigators have reported low vitamin E concentrations and suggested oxidative stress injury; others have found elevated concentrations of acetylcholinesterase in CSF. The cause of this disorder remains to be discovered.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Gross lesions in the CNS are not present in dogs with age-related degenerative myelopathy; however, atrophy of caudal axial and appendicular muscles occurs. Microscopic lesions are most notable in the thoracic spinal cord and can be diffuse or multifocal. Dorsal aspects of the lateral and ventromedial areas of ventral funiculi can be more severely affected, but lesions can be diffuse in all funiculi. Lesions consist predominately of ballooning and degeneration of myelin sheaths and less prominently of axonal degeneration and loss. Degeneration of dorsal nerve rootlets and peripheral nerves and loss of neuron cell bodies in spinal gray matter occur as well.

Clinically, affected dogs are usually older than 8 years, but the disease has occurred as early as 5 years of age. They have progressive ataxia referable to the thoracolumbar spinal cord and muscle weakness.

14.1.2.3.1.2

### Aminoacidopathies

Two diseases characterized by errors of amino acid metabolism have been described in neonatal calves. One disease, designated maple syrup urine disease (MSUD), occurs in young polled Hereford and Hereford calves. The second disease, bovine citrullinemia, which was originally described in Australia, occurs in neonatal Friesian calves.

MSUD is caused by an inherited defect in branched chain keto-acid dehydrogenase enzyme complex necessary to metabolize the branched-chain amino acids leucine, isoleucine, and valine. These amino acids are essential and must be obtained from protein in the diet. Following consumption, proteins are digested and the amino acids are released to be used to generate energy and for other metabolic processes. In MSUD there is a mutation in one or more of the genes that regulate this degradation process; therefore abnormal metabolites and ketoacids accumulate to toxic levels and cause disease. Urine has a sweet odor attributable to a derivative of isoleucine resembling maple syrup. In human infants the disease is confirmed biochemically by finding elevated concentrations of leucine, isoleucine, and valine in the blood.

Gross lesions are not typically present. Microscopically, marked spongiosis, due to vacuolation of myelin sheaths, is present throughout the neuraxis. The spongiosis affects both gray and white matter. Lesions are often most notable in areas such as the brain stem, where there is an intermingling of gray and white matter.

Affected calves may be normal at birth. Within a few days depression, dullness, and weakness progress to recumbency and opisthotonus.

Bovine citrullinemia is a rare inborn error of metabolism of the urea cycle that results in a pronounced accumulation of citrulline and ammonia in the body fluids because of a failure of the normal synthesis of arginosuccinic acid by the enzyme arginosuccinate synthetase. In human infants the disease is confirmed biochemically by finding elevated concentrations of citrulline in the blood. The cerebral lesions have also been suspected to result from the hyperammonemia or possibly some defect in excitatory neurotransmitter metabolism. However, the pathogenesis of the disease in calves remains unsettled.

Grossly, brains appear normal and have normal weights. Livers are pale yellow. Microscopically, there is fatty change in the liver. Lesions in the brain are characterized by mild to moderate diffuse astroglial swelling in the cerebral cortex.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Calves are normal at birth. Within a few days a severe generalized CNS disorder develops characterized by apparent blindness, depression, and tremors that rapidly progress to seizures, coma, and death within a few hours.

14.1.2.3.1.3

### Cerebral Cortical Atrophy

Brain atrophy caused by the loss of neurons in the cerebral cortex can occur in animal species but is observed most commonly in sheep with lipofuscinosis. Lipofuscin pigment, a “wear and tear” pigment associated with low-grade chronic membrane damage via lipid peroxidation, is often found in affected neurons. The cause of this lesion is unknown but thought to be related to long-term “wear and tear” on the CNS. Atrophy most frequently involves the cerebral hemispheres, especially the cortex. The cerebral hemispheres are increased in firmness often have a tan color (lipofuscin), and gyri are thinned and the sulci widened. Microscopically, there is loss of neuron cell bodies in cortical laminae without inflammation. Astrogliosis in response to neuronal loss is also observed, as is an increased prominence of the adventitial layer of blood vessels.

901

902

14.1.2.3.1.4

### Channelopathies

Channelopathies are a newly emerging group of inherited neuromuscular diseases of human beings that affect the excitability of membranes of neurons and skeletal myocytes. These diseases result from mutations in genes encoding ion channel proteins that regulate calcium, sodium, and chloride channels and acetylcholine receptors. In human beings, neurologic diseases—such as epilepsy and migraine headaches—have been attributed to channelopathies. In veterinary neurology, channelopathies will likely be shown, in the future, to be the underlying mechanism for epilepsy and other primary neuronal degenerations.

14.1.2.3.1.5

### Degenerative Leukomyelopathies

Degenerative leukomyelopathies are a heterogeneous group of familial, likely inherited, and acquired diseases that have been described in dogs, cows, and horses. Although there is not universal agreement, the degenerative leukomyelopathies described here are best characterized as axonal degenerations with spheroid formation predominantly within spinal cord white matter and secondary changes in myelin sheaths and myelin loss. In dogs, familial or inherited diseases include degenerative axonopathy of Ibizan hounds, axonopathy in Labrador retrievers, and axonopathy in Jack Russell and smooth fox terriers. A disease in rottweilers (covered under Primary Cerebellar Neuronal Degenerations in Dogs and Cats) is another disorder with spinal cord white matter involvement that is familial and possibly inherited. An acquired disease, hound ataxia, has been described in the United Kingdom and Ireland in harrier, beagle, and foxhounds. Hound ataxia may represent a nutritional disorder in hunting dogs fed paunch (tripe). Degenerative leukomyelopathies in cattle can be inherited as an autosomal recessive trait or have a familial predisposition. Leukomyelopathies have been reported in Murray Grey, Holstein-Friesian, and in certain lines of Brown Swiss cattle. In horses, a degenerative leukomyelopathy, covered separately next, is recognized that does not seem to have a well-defined familial or hereditary basis.

Gross lesions are usually not observed. Microscopically, lesions in the white matter of the spinal cord are bilaterally symmetrical and consist of axonal degeneration with formation of spheroids, loss of axons, and secondary myelin degradation. Depending on the species or breed affected, lesions can

902

involve any of the funiculi. Spinocerebellar tracts in the dorsolateral aspects of the lateral and septomarginal areas of ventral funiculi are commonly affected, as is the fasciculus gracilis in the dorsal funiculus. Severe involvement of the dorsal spinocerebellar tracts can extend into the caudal brain stem and via caudal cerebellar peduncles to the cerebellar cortex and Purkinje cells. In some species and breeds, there can also be involvement of additional specific brain stem structures.

Age of onset varies with the familial or inherited disorders. Paresis, ataxia, and dysmetria are the predominant clinical signs.

### 14.1.2.3.1.6

#### Equine Degenerative Myeloencephalopathy

Equine degenerative myeloencephalopathy has been reported in a variety of pure and mixed breed horses. A similar disease has been reported in zebras. The specific cause of this disorder is unknown. Although a firm relationship does not currently exist, there is some evidence to suggest that vitamin E deficiency could play a role in this disease as well as in a disorder in Morgan and Haflinger breeds termed neuraxonal dystrophy. Investigators have found low vitamin E levels in some horses and that vitamin E supplementation has resulted in clinical improvement or reduced the occurrence of the disease on some premises with a high incidence of degenerative myeloencephalopathy.

Vitamin E functions as an antioxidant, protecting cells from free radical-mediated injury. Vitamin E deficiency associated with abetalipoproteinemia and various fat malabsorption syndromes in human beings, as well as experimentally induced deficiency, result in neurologic disorders with similarities to the equine diseases. A hereditary predisposition for equine degenerative myeloencephalopathy has not been excluded, but a specific mechanism has so far been elusive. Although this disease might be multifactorial or even represent entirely different syndromes with overlapping clinical presentations and lesions, they are grouped here because of similarities in clinical presentation and lesions.

In horses with degenerative myeloencephalopathy, lesions are microscopic. Axonal degeneration in the spinal cord is the most notable lesion, is bilateral, and can affect all funiculi, but the dorsal funiculus is least affected. Dorsal spinocerebellar tracts in lateral funiculi and septomarginal areas of the ventral funiculus are often severely affected. Myelin loss occurs secondary to the axonal degeneration. Depending on duration of clinical illness, astrogliosis occurs. Another, less dramatic, lesion in affected horses is the formation of eosinophilic spheroids (Fig. 14-67). In horses, spheroids have been described in the nucleus gracilis, medial and lateral cuneate nuclei of the terminal brain stem, and thoracic nucleus of the spinal cord. Spheroids represent a focal eosinophilic swelling in the course of an axon that can be somewhat homogeneous, laminated, or granular. The swellings are filled with amorphous debris, membranous profiles, and effete organelles.

**Fig. 14-67 Axonal spheroids and dystrophic axons, degenerative myeloencephalopathy, spinal cord, dorsal gray horn, horse.** Axons of the thoracic nucleus are swollen, rounded, and pale pink (axonal spheroids, which are accumulations of neurofilaments and effete organelles) (*arrows*). Although attributed to vitamin E deficiency, its role in central nervous system disease is not firmly established. Vitamin E functions as an antioxidant, protecting cells from free radical-mediated injury. H&E stain. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

A clinically similar syndrome occurs in Morgan and Haflinger horses; changes are termed neuroaxonal dystrophy. Lesions consist of eosinophilic spheroids in brain stem nuclei as previously noted, but the severe axonal degeneration does not occur in the spinal cord. The cause of axonal spheroids and dystrophic axons in equine degenerative myeloencephalopathy and neuroaxonal dystrophy is unclear; however, alteration of axoplasmic flow is suspected. Immunohistochemical analyses have shown that spheroids and dystrophic axons contain elevated quantities of proteins involved in movement, docking, and fusion of synaptic vesicles to plasma membranes. These findings suggest that disruption of axoplasmic flow plays a role in the pathogenesis of dystrophic axons in equine degenerative myeloencephalopathy and neuroaxonal dystrophy.

Clinically, equine degenerative myeloencephalopathy and neuroaxonal dystrophies typically occur in young horses. The onset is insidious and clinical signs are symmetric with spasticity, ataxia, and paresis of the limbs.

14.1.2.3.1.7

### Epileptic Brain Damage

Brain damage due to prolonged (usually >30 minutes) convulsive seizures (status epilepticus) is not widely recognized or its occurrence even accepted in domestic animals. In human beings and experimental animals, brain damage resulting from status epilepticus is well documented. One study reported a relatively high incidence of brain lesions in dogs caused by status epilepticus. In this study, acute brain damage was widespread and corresponded well with areas of the brain prone to hypoxic-ischemic injury, such as the cerebral cortex, pyriform cortex, basal nuclei, and hippocampus.

The cause of neuronal injury with prolonged convulsive seizures is debatable. It remains unclear if necrosis, apoptosis, or a combination of these two mechanisms cause neuronal injury in status epilepticus. During seizures, there is an increased metabolic demand for glucose and oxygen by neurons; however, cerebral blood flow increases during seizures, so that the amount of glucose and oxygen available for neurons to generate energy remains adequate, at least during earlier stages. Acute neuronal necrosis still occurs even when cerebral blood flow, oxygenation, body temperature, and other metabolic parameters are maintained within normal limits in experimental animals with status epilepticus.

Excitotoxic injury due to accumulation of neurotoxic amino acid neurotransmitters, such as glutamate during the extreme neuronal activity occurring in status epilepticus, is an attractive explanation for neuronal necrosis. Excitotoxicity would account for both the selective vulnerability of certain brain areas and the character of the lesions. Status epilepticus induced experimentally with kainic acid, an excitatory amino acid receptor agonist, in rats has been shown to cause primarily neuronal necrosis and some characteristics of apoptosis. Other experimental studies have suggested that astrocytes produce clusterin during status epilepticus. Clusterin (dimeric acidic glycoprotein), a sulfated glycoprotein, when expressed in cells in elevated concentrations initiates apoptosis. It is proposed that clusterin secreted by astrocytes during status epilepticus is actively endocytosed by hippocampal neurons, and these neurons die by an apoptotic mechanism. The exact mechanism of neuronal injury remains to be proven. There is some evidence that the mature brain is more prone to injury induced by status epilepticus than the immature brain.

Gross lesions, if present, usually consist of widened and flattened gyri and narrow indistinct sulci	903
caused by cerebral edema. Acute neuronal ischemic cell change and astrocytic swelling are observed microscopically. In experimental animals with status epilepticus, neuronal degeneration is observed within 30 minutes and neuronal necrosis within 60 minutes.	904

14.1.2.3.1.8

### Hepatic Encephalopathy

Acute and chronic liver failure, as well as hepatic atrophy associated with congenital or acquired vascular shunts, often results in hepatic encephalopathy and disordered neurotransmission because of the accumulation of toxic substances, principally ammonia, in the systemic circulation and thus the CNS. Ammonia is formed in the gastrointestinal tract by bacterial degradation of amines, amino acids, purines, and urea from proteins consumed in the diet. In healthy animals, ammonia is detoxified in the liver by conversion to urea by the ornithine citrulline arginine urea cycle. Urea is far less toxic than ammonia and is excreted in the urine. Ammonia has several neurotoxic effects such as: (1) changing the transit of amino acids, water, and electrolytes across the neuronal cell membranes and (2) inhibiting the generation of both excitatory and inhibitory postsynaptic potentials in neurons. Ammonia and other

## Pathologic Basis of Veterinary Disease, 4th Edition

---

toxic metabolites also appear to (1) cause increased permeability of the blood-brain barrier leading to vasogenic edema and (2) alter osmoregulation within the CNS. These mechanisms likely led to the spongy change (status spongiosus) characteristic of the disease microscopically. Because astrocytes play an important role in regulating fluid and electrolyte balances in the CNS and are the primary cell type having lesions (Alzheimer's type II astrocytes) in hepatic encephalopathy, it is not surprising that alterations in osmoregulation are a component of the pathogenesis of the disease. Ammonia and other toxic metabolites likely also affect oligodendroglia. Finally, it has been proposed that alterations in the blood-brain barrier may facilitate passage of neurotoxins, such as short-chain fatty acids, mercaptans, false (pseudo-) neurotransmitters (tyramine, octopamine, and  $\beta$ -phenylethanolamine), ammonia, and GABA into the CNS leading to neuronal dysfunction. A similar condition, termed renal encephalopathy, has been described in dogs, a horse, and a cow with renal failure. It is likely related to high concentrations of ammonia or ammonia-metabolites in the circulation because of inadequate renal clearance caused by severe glomerular or tubular injury.

In all species except the horse, lesions of hepatic encephalopathy are of two types: spongy change and formation of Alzheimer's type II astrocytes (Fig. 14-13, D). Spongy change can be present throughout the neuraxis but typically involves areas of confluence or intermingling of gray and white. These areas include the deep cerebrocortical gray-white matter interface, basal nuclei and adjacent internal capsule, reticular areas throughout the brain stem, and deep cerebellar nuclei. The spongy change is due to intramyelinic edema, causing splitting and vacuolation of myelin sheaths. Spongy change can be produced experimentally by ammonia infusion and is reversible. Alzheimer's type II astrocytic change is a subtle alteration but has been reported in all domestic animals and is the only CNS change observed in horses with hepatic failure. Alzheimer's type II astrocytes are found in gray matter and have enlarged vesicular nuclei with peripheral chromatin, glycogen deposits, and demonstrable nucleoli or nucleolar-type bodies. Immunocytochemical staining for GFAP is typically weak or absent, possibly indicating a toxic effect on astrocytes.

Clinically, affected animals show CNS signs such as seizures, ataxia, depressed mentation, walking aimlessly, and head pressing.

14.1.2.3.1.9

### Mitochondrial Encephalopathies

In human beings, various encephalopathic and myopathic syndromes due to point mutations in mitochondrial DNA affecting tRNA genes are grouped under the acronyms MELAS (mitochondrial encephalopathy, lactic acidosis, stroke-like episodes) and MERRF (myoclonus epilepsy, ragged red fibers). The various human syndromes include Leigh's disease (subacute necrotizing encephalomyelopathy), Kearns-Sayre syndrome, and Leber's hereditary optic atrophy.

Diseases that might be classified as mitochondrial encephalopathies are not well characterized in animals. Despite this caveat, the diseases reported in the Alaskan husky, Australian cattle dogs, English springer spaniel dogs, and a Jack Russell terrier, as well as in Limousin and Simmental cattle and New Zealand South Hampshire sheep, could represent mitochondrial disorders. Table 14-7 summarizes the salient features of the diseases. Characteristics of these diseases in both human beings and animals are symmetric bilateral involvement of the neuraxis and lesions typified by status spongiosus (edema of cerebral white matter) with variable progression to cavitation or necrosis. The CNS is highly dependent on oxidative metabolism and is therefore the most severely affected organ in mitochondrial disorders. Mitochondria isolated from affected human patients have impaired oxygen consumption and reduced respiratory chain enzyme complex activity. Recently, although quite controversial, it has been suggested that alterations in the function of genes in endothelial cells cause dysfunction of the

## Pathologic Basis of Veterinary Disease, 4th Edition

blood-brain and CSF-blood barriers, which may play an important role in the underlying pathogenesis of mitochondrial encephalopathies.

14.1.2.3.1.10

### Primary Neuronal Degeneration

The term *primary neuronal degeneration* encompasses three groups of diseases affecting specific regions of the CNS in a temporally and spatially stereotyped manner and are characterized by degeneration, necrosis, and loss of specific populations of functionally linked neurons. Table 14-8 gives an overview of these diseases. The first group includes the multisystem neuronal degenerations, diseases that affect populations of functionally related neurons in the basal ganglia, brain stem, and cerebellum. The second group includes the primary cerebellar neuronal degenerations, diseases that affect populations of neurons restricted to the cerebellum and cerebellar roof nuclei. The third group includes primary spinal cord degenerations, diseases associated with axonal swellings (axonal spheroids) in the neuraxis termed neuraxonal dystrophies. Another term used to denote some of these diseases in the biomedical literature and veterinary textbooks is “abiotrophy” introduced by Gowers in 1902. The term literally means lack of (“a”) a vital (“bios”) nutrition (“trophy”) required to sustain the life of a tissue.

904

905

Table 14-7 Possible Mitochondrial Encephalopathies in Animals

Animal	Age of Onset	Clinical Signs	Principal Lesions
Alaskan husky	6 to 9 mo	Ataxia, other motor disturbances, anxiety, blindness, hypalgesia	Spongiosis and cavitation in thalamus caudal to medulla
Cattle dog	5 to 12 mo	Seizures, behavioral abnormalities followed by locomotor signs	Spongiosis and cavitation in cerebellum, brain stem nuclei, and spinal gray matter
English springer spaniel	15 to 16 mo	Ataxia, disorientation, visual deficits	Status spongiosis in accessory olivary nucleus; axon loss and gliosis in optic nerve and tracts
Jack Russell terrier (Parson)	2.5 mo	Ataxia, hypermetria, and deafness	Neuronal degeneration and mineralization of the medulla oblongata, vestibulocochlear nerve, choroid plexus, and granule cell layer of the cerebellum
Limousin cattle	1 to 4 mo	Locomotor signs, aggressive behavior, blindness	Spongiosis, cavitation in cerebral and cerebellar white matter, brain stem nuclei, optic chiasm
Simmental cattle	5 to 12 mo	Ataxia, behavioral changes	Spongiosis and necrosis in internal capsule, caudate nucleus, putamen, brain stem nuclei, spinal gray matter

14.1.2.3.1.11 Multisystem Neuronal Degeneration

14.1.2.3.1.11.1 Progressive neuronal abiotrophy of Kerry blue terriers

Progressive neuronal abiotrophy of Kerry blue terriers (cerebellar cortical and extrapyramidal nuclear abiotrophy of Kerry blue terriers, abiotrophy of Kerry blue terriers, or hereditary striatonigral and cerebello-olivary degeneration of Kerry blue terriers) is a well-characterized example of a disease with multisystem neuronal degeneration. The disease is inherited and affects connected neural systems, including basal nuclei and the substantia nigra (i.e., striatonigral), and the cerebellar cortex and caudal olivary nucleus (cerebello-olivary).

Bovine—Brown Swiss, Holstein-Friesian, Murray gray

Equine—Various breeds (see vitamin E deficiency)

The pathogenesis is unknown, but an excitotoxic mechanism associated with abnormalities in the glutaminergic cortico-striatal and in the granule–Purkinje cell neurotransmitter systems is proposed. The caudate nucleus and cerebellar cortex are believed to be the primary sites of involvement, whereas lesions in the olivary nucleus and substantia nigra represent transsynaptic degeneration.

Gross lesions are a slight reduction in size of the cerebellum and narrowing of cerebellar folia (Fig. 14-68). In more advanced stages, small foci of softening and discoloration occur in the caudal olivary nucleus and substantia nigra (Fig. 14-69). Lesions in the caudate nucleus initially consist of a vague area of pallor in the body of the nucleus that progresses to marked malacia and ultimately cavitation. There can be similar involvement of the putamen at this advanced stage. Microscopic lesions in chronologic order are degeneration and loss of cerebellar Purkinje and granule cells, followed by neuronal loss in the caudal olivary nucleus, caudate nucleus, putamen, and substantia nigra. Astrogliosis occurs in later stages and is especially prominent in the cerebellar molecular layer. The caudate nucleus and putamen are eventually reduced to microcystic cavities bisected by a few nerve and glial fibers.

Fig. 14-68 **Striatonigral and cerebello-olivary degeneration, brain, cerebellum, Kerry blue terrier.** Marked atrophy and thinning of folia of dorsal cerebellum (*arrows*) has resulted in increased width of sulci. 906

In Kerry blue terriers this hereditary disease, with onset from 5 weeks to 5½ months of age, is characterized clinically by rear limb ataxia, intention tremors, hypermetria of front and rear limbs, and atrophy of appendicular and epaxial muscles, presumably from disuse.

907

14.1.2.3.1.11.2

### Multisystem neuronal degeneration of the red-coated English cocker spaniel

Multisystem neuronal degeneration of the red-coated English cocker spaniel is suspected of being inherited. The pathogenesis is unknown. Bilaterally symmetric diffuse nerve cell loss, astrogliosis, and axonal swellings occur in several nuclei, including septal nuclei, globus pallidus, subthalamic nuclei, substantia nigra, tectum, medial geniculate bodies, and cerebellar and vestibular nuclei. Central cerebellar white matter, corpus callosum, thalamic striae, and subcortical (particularly subcallosal gyri) white matter involvement also are noted. White matter lesions consist of axonal spheroids, intense astrogliosis, subtle myelin loss, and perivascular accumulation of macrophages. Clinical signs occur during the first year of life and consist of progressive ataxia and mental deterioration.

14.1.2.3.1.11.3

### Multisystemic neuronal degeneration of the Cairn terrier

Multisystemic neuronal degeneration of the Cairn terrier has features of an inherited disorder. The pathogenesis is unknown. Widespread neuronal chromatolysis affecting multiple neuronal systems is observed in the CNS and PNS. Affected areas include brain stem sensory and motor nuclei, cerebellar roof nuclei, ventral and dorsal gray columns of the spinal cord, and spinal and autonomic ganglia. Other lesions include degeneration in lateral and ventral spinal funiculi, necrosis of substantia gelatinosa and adjacent white matter most notable in caudal thoracic and cranial lumbar segments, and degeneration in dorsal and ventral spinal nerve rootlets and peripheral nerves. Clinical signs occur between 2½ and 5 months of age, and there is onset of progressive cerebellar ataxia, spastic paresis, and collapse.

14.1.2.3.1.12

### Primary Cerebellar Neuronal Degeneration

Depending on the degree of maturation of the cerebellum and related systems at the time of birth in the various species, clinical signs in animals with the neonatal syndromes can be manifest in the immediate postnatal period (bovine, ovine) or can be delayed until the time of ambulation (canine). Hereditary transmission is known or suspected in some instances. Lesions vary among affected species and breeds but overall include degeneration or absence of Purkinje cells, proximal swelling of Purkinje cell axons, variable loss of granule cells, cortical astrogliosis, and degeneration of nuclei in the cerebellar medulla.

Animals with postnatal cerebellar syndromes are normal at birth or at the time of ambulation. Onset of ataxia with various other clinical signs referable to cerebellar disease begins weeks or months after a period of apparently normal development. Initial clinical signs are often subtle. Progression of the signs can be slow or rapid, relentless, or with static periods. Some individuals reach a stage without further progression of signs, but this is not typical of the syndrome in most animals.

Grossly the cerebellum can be normal or reduced in size and atrophic. Microscopically, lesions are analogous to those that occur in the neonatal syndromes with loss of Purkinje cells, variable neuronal depletion in the granular layer, and astrogliosis in the molecular layer. Fusiform swellings of proximal Purkinje cell axons are found in the rough-coated collie and the Yorkshire pig. In the rough-coated collie and Merino sheep, lesions occur in other areas of the neuraxis. In these syndromes, degeneration and loss of neurons in the deep cerebellar and other nuclei are accompanied by axonal degeneration in the cerebellum, brain stem, and spinal cord. Loss of spinal ventral horn motor neurons has been noted in the rough-coated collie. An autosomal recessive mode of inheritance is suspected or documented in several of the diseases.

14.1.2.3.1.12.1

### Primary cerebellar neuronal degeneration in dogs and cats

Primary cerebellar neuronal degenerations, as described previously, have been reported to occur in many breeds of dogs and cats, such as American Staffordshire terriers, Australian kelpie dogs, Italian hounds, border collies, Brittany dogs, beagle dogs, Portuguese podengo dogs, Scottish terriers, and domestic shorthair cats. This list is not inclusive and serves only to provide a few common examples. Although most common in young animals of the breeds listed, cerebellar degeneration in Brittany dogs occurs between 7 and 14 years of age. An autosomal recessive mode of inheritance is suspected or documented in several of the diseases. Grossly, the cerebellum can be normal or reduced in size and atrophic. Microscopically, the distribution and characteristics of

## Pathologic Basis of Veterinary Disease, 4th Edition

lesions will vary depending on the breed and species of animal affected. A detailed discussion of the microscopic lesions for each breed and species is outside the scope of this chapter; however, lesions may include a combination of the following changes: loss of Purkinje cells and neurons of the granular layer, astrogliosis, fusiform swelling of proximal Purkinje cell axons, and axonal degeneration in the cerebellum, brain stem, and spinal cord.

Recently, neuronal vacuolation and spinocerebellar degeneration has been reported in young rottweiler dogs. This breed variant of primary cerebellar neuronal degeneration raised biomedical concerns because of the similarities between the vacuolar lesions in neurons of this disease and those of the TSEs (scrapie, BSE). Analyses for protease-resistant scrapie prion protein were performed and were negative. The cause of this disease has not been determined but appears to have a hereditary basis. Apoptotic cell death is apparently not involved in neuronal degeneration. No gross lesions are observed in the brain, but atrophy of the dorsal cricoarytenoid muscles of the larynx has been reported. Microscopic lesions are characterized by spongiform change affecting neuron cell bodies and the neuropil. The cytoplasm of neurons of the cerebellar roof nuclei and nuclei of the extrapyramidal system contain one or more clear vacuoles (1 to 45 µm in diameter). Similar vacuoles are found in neurons in both dorsal nerve root ganglia, myenteric plexus, and other ganglia of the autonomic nervous system. Purkinje cells are also vacuolated, and in terminal stages of the disease there is degeneration with segmental Purkinje cell loss.

Clinical signs, seen as early as 6 weeks (commonly between 3 and 8 months of age in both sexes), include generalized weakness, ataxia, proprioceptive deficits, and paresis that progress in severity over the course of the disease.

14.1.2.3.1.12.2

### Primary cerebellar neuronal degeneration in livestock

Primary cerebellar neuronal degeneration has also been reported to occur in Yorkshire piglets, Merino and Charollais lambs, Holstein Friesian calves, Angus calves, and a moose. An autosomal recessive mode of inheritance is suspected or documented in several of the diseases, but the mechanism of injury is unclear. Grossly the cerebellum can be normal or reduced in size and atrophic. Microscopically, lesions may include loss of Purkinje cells, variable neuronal depletion in the granular layer, fusiform swellings of proximal Purkinje cell axons, and astrogliosis in the molecular layer.

Animals with postnatal primary cerebellar neuronal degeneration are normal at birth or at the time of ambulation. Onset of ataxia with various other clinical signs referable to cerebellar disease begins weeks or months after a period of apparently normal development. Initial clinical signs are often subtle. Progression of the signs can be slow or rapid, relentless, or with static periods. Some individuals reach a stage without further progression of signs, but this is not typical of the syndrome in most animals.

14.1.2.3.1.12.3

### Primary cerebellar neuronal degeneration in horses

Equine cerebellar abiotrophy, a primary cerebellar neuronal degeneration, occurs in Arabian or part-Arabian foals and Swedish Gotland ponies. An autosomal recessive mode of inheritance is suspected, but the mechanism of injury is unclear. Although grossly the cerebellum may be slightly reduced in size, microscopically Purkinje cells and their proximal axons are swollen (Fig. 14-70). With time, there may be loss of Purkinje cells and neurons of the granular layer. Clinical signs

## Pathologic Basis of Veterinary Disease, 4th Edition

appear between the time of birth and 9 months of age and include head tremors, ataxia, and spasticity.

**Fig. 14-70 Equine cerebellar degeneration, cerebellum, horse.** Purkinje cells in the cerebellum show changes consistent with necrosis, such as shrunken cell bodies and nuclear pyknosis (*arrows*). H&E stain. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

14.1.2.3.1.12.4

### Neuraxonal dystrophy

Diseases associated with axonal swellings (axonal spheroids) have been termed neuraxonal dystrophy. Diseases include those putatively associated with vitamin E deficiency or that have been interpreted as an aging change (also see Degenerative Leukomyelopathies and Vitamin E Deficiency). Included here are diseases with a species and breed association and onset relatively early in life, generally before 1 year of age but varying between 4 weeks and 3 years. A hereditary basis is often suspected or proven. Neuraxonal dystrophies have been described in dogs, cats, horses, and sheep. Dystrophy is defined as a disorder arising from defective or faulty nutrition of a cell, tissue, or organ, and the term is most commonly applied to muscle diseases. In this usage it applies to neurons and their axons (neuraxonal). Lesions differ in severity and distribution but are characterized by prominent axonal swellings in various nuclei (often sensory) in the brain stem, cerebellum, and spinal cord. Loss of cerebellar Purkinje and granule cells have been reported in rottweilers and cats and loss of brain stem neurons in cats. In the Morgan horse the axonal swellings are associated with vacuolation.

908

Neuroaxonal dystrophies are often characterized clinically by severe and often profound muscular weakness and widespread muscle atrophy. Sporadic cases in older adult animals also occur of unknown cause or suspected extraneous influence. Clinical signs vary but include gait abnormalities, dysmetria or hypermetria, proprioceptive disturbance, ataxia, or other cerebellar signs.

909

14.1.2.3.1.12.5

### Motor neuron diseases

Motor neuron diseases have been described in dogs, cats, cows, horses, and pigs. Degeneration and loss of motor neurons in the ventral horns of the spinal cord and variable axonal degeneration in the ventral spinal nerve rootlets and peripheral nerves characterize the lesions in motor neuron diseases. In some of the motor neuron diseases, there is prominent swelling of ventral horn neuronal cells bodies or axons, or both, associated with marked accumulation of neurofilaments. This accumulation is presumably due to posttranslational protein modification and impairment of neurofilament protein transport. Degeneration in some diseases is not strictly limited to motor neurons of the spinal cord or to motor neurons in general. Other sites of involvement are motor or sensory nuclei, or both, in the brain stem and white matter tracts in the spinal cord.

In horses, lesions in motor neurons are analogous to those already described. The disease affects various breeds, no definitive familial association or age predilections are known, and an inherited basis is not suspected. Generalized weakness, muscle atrophy, and weight loss progress over 1 to several months.

In calves, a disease known as shaker calf syndrome in horned Hereford calves can only be loosely termed a motor neuron disease. There is marked accumulation of neurofilaments within neurons of the central, peripheral, and autonomic nervous systems. All segments of the spinal cord are severely affected. Neurons and neuronal processes in ventral horns, intermediolateral nucleus, Clarke's column, and substantia gelatinosa are swollen and distended. Wallerian degeneration occurs in ventral nerve rootlets and white matter of the spinal cord. Brain stem lesions are less prominent. Swollen cerebellar Purkinje cells and neuronal degeneration in the lateral geniculate body and frontal cortex are reported. The disorder occurs in newborn calves and is characterized clinically by tremulous shaking of the head, body, and tail.

14.1.2.3.2

### NUTRITIONAL

14.1.2.3.2.1

#### Copper

Swayback and enzootic ataxia are diseases caused by copper deficiency in lambs and kid goats. *Swayback* refers to the congenital form of the disease, whereas in enzootic ataxia, onset is delayed for up to 6 months after birth. Although copper deficiency is involved, the pathogenesis is poorly understood. Lesions occur in the cerebrum, brain stem, and spinal cord in the congenital form, but only in the brain stem and spinal cord in cases with a postnatal onset.

Additionally, deficiency of copper can affect wool, hair growth, and pigmentation; musculoskeletal development; and integrity of connective tissue. Copper deficiency can be primarily due to copper-deficient soils and inadequate intake from forage or secondary from defective absorption because of interactions between copper, molybdenum, zinc, cadmium, or inorganic sulfates. Copper is a component of several enzyme systems—including cytochrome and lysyl oxidases such as mitochondrial cytochrome-c oxidase, dopamine  $\beta$ -monooxygenase, peptidyl  $\alpha$ -amidating monooxygenase, tyrosinase, and superoxide dismutase—and the protein ceruloplasmin. These enzyme systems are essential for energy generation by mitochondria in the brain, regulating oxidative stress, catecholamine synthesis, and the modification of peptide neurotransmitters.

The pathogenesis of the lesions that occur in swayback and enzootic ataxia is poorly understood. It has been suggested that cerebral lesions result from loss of embryonic cells at the same stage of brain development as occurs in porencephaly and hydranencephaly following in utero viral infection or dysgenesis caused by a biochemical disturbance. Biochemical disturbances could also account for the axonal/neuronal degeneration in the brain stem and spinal cord. Altered function of the mitochondrial enzyme cytochrome oxidase leading to energy failure could play a role in cerebral dysgenesis and axonal and ultimately neuronal degeneration.

More intriguing is the possible involvement of the enzyme copper-zinc superoxide dismutase. A mutation in this enzyme is present in approximately 20% of human beings with familial amyotrophic lateral sclerosis (ALS) and in some individuals with the sporadic form of the disease. This human disorder, which is classified as a motor neuron disease, has a much later onset, and the mutation results in a “gain of function” of the enzyme rather than lack of function as might be present in copper deficiency. Neurofilament accumulation in brain stem and spinal ventral horn neurons and fiber tract degeneration (corticospinal in human beings versus spinocerebellar in lambs and kids with copper deficiency) are similar. Drawing a relevant association between these diseases of human beings and abnormal function of superoxide dismutase in swayback and enzootic ataxia in animals is premature at this time, however. It is also possible that the cortical white matter degeneration and brain stem or spinal lesions arise from different mechanisms.

Grossly, approximately 50% of congenitally affected lambs and rarely kids have bilateral cerebrocortical lesions. Externally the cerebral cortex can be focally soft and fluctuant or collapsed. 909 910

These foci correspond to areas of rarefaction, which have either a gelatinous consistency or cystic cavities filled with clear serous fluid, in the white matter of the corona radiata and centrum semiovale. Microscopically a variable astrogliosis is associated with the degeneration of white matter, but the cavities lack a capsule of glial fibers. Myelin degradation and an influx of macrophages are minimal. Delicate neuronal and astroglial processes traverse the cavities. Neuronal necrosis in cortical gray matter overlying these white matter lesions is sometimes observed.

Microscopic lesions in the brain stem and spinal cord in both the congenital (swayback) and delayed-onset (enzootic ataxia) forms of copper deficiency are similar in lambs and kids, and they affect both gray and white matter. Large multipolar neurons of the brain stem reticular formation, certain brain stem nuclei—such as the red and vestibular nuclei—and the ventral, lateral, and, less commonly, dorsal horns of the spinal cord are affected. Neuronal cell bodies lack stainable Nissl's substance (chromatolysis). The cytoplasm is variably dense, pink, and homogeneous to fibrillar as a result of the accumulation of neurofilaments, and nuclei are often displaced to an eccentric position against the cell membrane. The extent of neuronal necrosis varies. Lesions in the white matter of the spinal cord consist of bilateral areas of pallor in the dorsolateral aspects of the lateral funiculi (corresponding roughly to the spinocerebellar tracts) and also in the ventral funiculi adjacent to the ventral median fissure. The pallor of the white matter is due to degeneration of myelinated axons. Involvement of the medial (septomarginal) aspect of the dorsal funiculi is infrequent. In the terminal brain stem, lesions are similar but have a somewhat scattered distribution. The spinocerebellar tracts extending into the middle cerebellar peduncles are affected. Astrogliosis is usually mild. Definitive microscopic lesions in the cerebellum and ventral spinal nerve rootlets and peripheral nerves are usually lacking in lambs, but can be frequent in kids. Changes in Purkinje cells are analogous to those already noted in neurons in other areas. Additionally, ectopic Purkinje cells and thinning of the granular cell layer occur. Bergmann's glial cell processes in the molecular layer hypertrophy. Lesions in ventral

## Pathologic Basis of Veterinary Disease, 4th Edition

spinal nerve rootlets and peripheral nerve are caused by axonal degeneration secondary to injury of motor neurons in the ventral gray horns.

Clinically, CNS disease due to copper deficiency in animals is mainly a disorder of sheep and goats and can be present at birth (swayback in lambs, rarely kids), or onset can be delayed up to 6 months (enzootic ataxia in lambs and kids). Swayback occurs in newborn lambs from ewes with inadequate dietary copper intake. Affected lambs can be born dead, weak, or unable to stand. If mobile, they are ataxic. Enzootic ataxia is characterized by ataxia.

14.1.2.3.2.2

### Vitamin B<sub>1</sub> (Thiamine) Deficiency

Thiamine diphosphate is the active form of thiamine. It is a critical cofactor for several thiamine-dependent enzymes involved in carbohydrate metabolism, and brain damage is thought to be related to a decline in thiamine-dependent enzymes, energy deprivation, and oxidative stress with the abnormal metabolism of free radicals in neurons. These enzymes are also important in the synthesis of several cell constituents, including neurotransmitters. Thiamine deficiency has been associated with neurologic disease in carnivores (Chastek paralysis), human beings (Wernicke's encephalopathy), and ruminants.

14.1.2.3.2.2.1

#### Thiamine deficiency in carnivores

In monogastric carnivores and human beings, the relationship between neurologic disease and thiamine deficiency per se is firmly established, and lesions in these species are similar. In carnivores (dog, cat, mink, fox) there is an absolute dietary requirement for vitamin B<sub>1</sub>. Dietary factors such as the ingestion of fish containing thiaminase, deficient diets, or diets in which the vitamin has been destroyed by other means such as heating, can all lead to thiamine deficiency.

Gross and microscopic lesions are bilaterally symmetric and commonly involve brain stem nuclei, especially caudal colliculi and periventricular nuclei, but the cerebral cortex and cerebellum have also been affected (Fig. 14-71). Lesions consist of neuronal degeneration, neuronal necrosis, status spongiosus, myelin degeneration, and a secondary vascular endothelial and perithelial cell hypertrophy and hyperplasia. Necrotic neurons are those in the caudal colliculi (auditory nerves) that project via axons to the medial geniculate nucleus and those whose cell bodies are located in the periventricular nuclei of the hypothalamus that regulate the release of endocrine hormones from the anterior pituitary. Hemorrhage and an influx of macrophages also occurs in some cases.

Clinical signs in carnivores may include a combination of the following: anorexia, vomiting, depression, wide-based stance, ataxia, spastic paresis, circling, seizures, muscle weakness, recumbency, opisthotonus, coma, or death.

14.1.2.3.2.2.2

#### Thiamine deficiency in ruminants

The disease in cattle, sheep, and less commonly, goats, has been termed polioencephalomalacia or cerebrocortical necrosis. Rumen microbes are able to synthesize thiamine, and conclusive evidence of an absolute thiamine deficiency as the sole cause of polioencephalomalacia in ruminants has been elusive. Evidence or theories linking thiamine with the ruminant disorder include the following:

1. Clinical response to thiamine injection in some individuals

910

911

## Pathologic Basis of Veterinary Disease, 4th Edition

---

2. Decreases in ruminal thiamine, or overgrowth of thiaminase-producing microbes, such as *Bacillus thiaminolyticus*
3. Ingestion of thiaminase-containing plants, such as bracken fern
4. Production of inactive thiamine analogs
5. Decreased absorption or increased fecal excretion of thiamine

**Fig. 14-71 Thiamine deficiency encephalopathy, midbrain, caudal colliculi, dog.** In the dog, lesions of thiamine deficiency encephalopathy are generally restricted to the brain stem. Note the symmetrically cavitated (malacic) lesions in the caudal colliculi (*arrows*) resulting from neuronal necrosis. (Courtesy Dr. J. Edwards, College of Veterinary Medicine, Texas A&M University; and Dr. J. King, College of Veterinary Medicine, Cornell University.)

Gross lesions, if present, are limited primarily to the cerebral cortex. Initially, 2 days after onset, the surface of the brain can be swollen (cerebral edema) as indicated by flattening of cerebrocortical gyri and narrow sulci. In rare cases with more severe brain swelling, brain displacement with herniation of the parahippocampal gyri beneath the tentorium cerebelli and the vermis of the cerebellum into

## Pathologic Basis of Veterinary Disease, 4th Edition

the foramen magnum can occur. By 4 days after onset, yellow discoloration of the cerebrocortical gray matter occurs (Fig. 14-72), and it is at this time that autofluorescence (see later for more detail) is seen when the brain is examined under 375 nm ultraviolet light (Fig. 14-73). Eight to 10 days after onset, edematous separation and necrosis involving the middle to deeper lamina or gray-white matter interface may be appreciable (Fig. 14-74). In advanced cases with prolonged survival, areas of marked atrophy of cerebral gyri with an attenuated or absent gray matter zone are covered by meninges (Fig. 14-75).

**Fig. 14-72 Acute polioencephalomalacia, cerebral cortex, cross-sectional view, cow.** Cerebral cortical gyri are yellow and swollen (*arrows*). The cause of this yellow color is unknown, but has been shown experimentally not to be caused by ceroid-lipofuscin pigments. Changes involving the sulci and gyri in acute polioencephalomalacia are shown in Fig. 14-31. (Courtesy Dr. L. Roth, College of Veterinary Medicine, Cornell University.)

Microscopically the earliest lesions are laminar cortical necrosis and astrocytic swelling. Laminar cortical necrosis is characterized by neuronal necrosis (ischemic change), with a laminar pattern of edema in the cerebral cortex. Neurons in the middle to deep lamina of the parieto-occipital lobes of the cerebral cortex are preferentially affected. In the early stages or in mild cases, lesions can be limited to the depths of cerebrocortical sulci, but generally there is involvement of entire gyri that may be confluent over extensive areas of the cortex. After 4 to 5 days, neuronal necrosis and edema are more severe, and there is an early influx of blood monocytes that mature into tissue macrophages and become gitter cells as they phagocytose necrotic debris. Macrophages and gitter cells are observed most commonly in perivascular and perineuronal spaces and in the pia arachnoid (Fig. 14-26, A). After 8 to 10 days, necrosis and edema have resulted in laminar separation (at the gray matter–white matter interface) in which there are prominent accumulations of macrophages (Fig. 14-76). Lesions that accompany the necrosis include vascular prominence caused by endothelial cell and perithelial cell hypertrophy and hyperplasia, congestion, and a minimal, if any, influx of neutrophils. Bilaterally symmetric focal lesions, similar to those seen in carnivores, occur in the thalamus and midbrain or colliculi and rarely in other brain stem structures. Animals that survive can

911

912

## Pathologic Basis of Veterinary Disease, 4th Edition

have cerebral atrophy and develop hydrocephalus ex vacuo and have been known to live 1 to 2 years. It should be noted that laminar cortical necrosis can be caused by a variety of metabolic abnormalities. In ruminants, in addition to thiamine deficiency, water deprivation-sodium ion toxicosis, lead poisoning, and high sulfur intake can cause polioencephalomalacia and laminar cortical necrosis. Although autofluorescence at 365 nm ultraviolet light has been historically attributed to the accumulation of ceroid-lipofuscin in lipophages resulting from lipid degeneration in injured neuronal cell membranes, this supposition has recently been questioned. A recent study of cerebrocortical necrosis reported that autofluorescent substances in degenerating neurons occurred in structures resembling mitochondria and that ceroid-lipofuscin pigments were not demonstrated microscopically in damaged CNS. An association between mitochondria and autofluorescence has also been shown in the neuronal ceroid lipofuscinoses (Batten disease, ceroid-lipofuscin storage diseases). These diseases are characterized by the accumulation of an autofluorescent (365 nm ultraviolet light), intracytoplasmic storage material in CNS neurons composed mostly of subunit c of mitochondrial ATP synthase.

912

913

**Fig. 14-73 Acute polioencephalomalacia, brain, cerebral hemispheres and midbrain, steer.** **A**, Compare the relative lack of gross lesions with those revealed by UV light in [Fig 14-73, B](#). **B**, Bilaterally symmetric laminar pattern of apple-green autofluorescence (from mitochondrial derivatives) involving the full-thickness of the cortex indicates areas of necrosis in the gray matter. Although not shown here, the colliculi were also autofluorescent. The cerebrum is exposed to 365 nm ultraviolet light from a Wood's lamp. Similar results can be obtained with fixed (preserved) brain. (*A and B*, Courtesy Dr H. Steinberg, School of Veterinary Medicine, University of Wisconsin-Madison.)

W, White matter. H&E stain. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

Clinically the disease is seen most commonly in cattle 6 to 18 months of age fed concentrated rations. In sheep, most cases occur in younger age groups (2 to 7 months). Clinical signs in cattle and small ruminants may include depression, stupor, ataxia, head pressing, apparent cortical blindness, opisthotonos, convulsions, and recumbency with paddling, and death. If animals survive or respond to therapy, clinical signs can persist.

Polioencephalomalacia commonly occurs in cattle fed rations rich in carbohydrates with little roughage and is also associated with clinical or subclinical acidosis that may precipitate changes in rumen microflora. The disorder also occurs in association with other dietary factors including cobalt deficiency, molasses- and urea-based diets, and with diets high in elemental sulfur and sulfates and sulfides, some of which are not specifically associated with thiamine deficiency.

Recently, there has been considerable interest in the relationship of high dietary sulfur to polioencephalomalacia. All sources of sulfur, including formulated rations, plants rich in sulfur (*Kochia scoparia*), and high concentrations of sulfur in the drinking water, are additive. Total dietary intake should not exceed 0.3% to 0.4%. The exact mechanism to explain sulfur-induced polioencephalomalacia in ruminants has not been proven. Although deficiency or disordered metabolism of thiamine can be involved, it would seem not to be the sole cause or, in some instances, even a major factor in the disorder. Alternatively, polioencephalomalacia could represent a multifactorial metabolic disorder with multiple causes, all culminating in cerebrocortical necrosis. Any unifying hypothesis concerning the mechanism(s) of brain damage would have to reconcile all these variables.

Space constraints do not allow a comprehensive discussion of all toxicities affecting the nervous system. [Table 14-9](#) is a partial listing of poisons with potential to cause neurologic illness and CNS injury. Some of these, such as mercury, have in the past caused high morbidity and mortality in isolated outbreaks. An example is the Minamata Bay incident in Japan (in 1956) of human beings eating fish containing high concentrations of methylmercury. Methylmercury accumulates in the aquatic food chain, and thus the highest concentrations exist in predatory fish at the top of the food chain. In human beings and animals with methylmercury toxicosis, neuronal cell bodies of the cerebral cortex and cerebellum die through a mechanism suggested to be apoptosis; however, microtubule dysfunction, oxidative stress, alterations of calcium homeostasis, and the potentiation of glutaminergic excitotoxicity may be involved. The potential remains for serious neurologic illnesses and death from these intoxications, and the interested reader is referred to more comprehensive reference sources. In this chapter, discussion of toxicities will be limited to those conditions most likely to be encountered in veterinary practice.

### 14.1.2.3.3.1 Chemicals

Chemically induced distal axonopathies have been classified by functional alterations affecting motor or sensory neurons, location of injury within the nerve (distal, proximal), or by the type of nerve affected (cranial or spinal). Because of the large number and wide use of chemicals in commerce, there

## Pathologic Basis of Veterinary Disease, 4th Edition

---

exists an extensive list of experimental studies describing toxic axonopathies and neuropathies. Their complete discussion is outside the scope of this chapter.

Chemicals used in agricultural, industrial, and pharmaceutical commerce can injure nerves by interfering with axoplasmic flow. Such chemicals include: acrylamide (polymerizing agent to strengthen paper), carbon disulfide (fat solvent, used for extraction of oil from oil-bearing fruit such as olives), triorthocresyl phosphate (high-performance lubricants in airplane engines), halomethane (refrigerants), methylene chloride (extraction agents, paint solvents, degreasing agents), carbon tetrachloride (solvents), and butane (fuel source).

Acrylamide causes a unique distal axonopathy (dying-back axonopathy) primarily affecting axons of the PNS (less commonly the CNS) in which there is accumulation of neurofilaments within affected axons. Axonal spheroids are thought to be related to alteration of axonal transport resulting from phosphorylation of neurofilaments and their abnormal rearrangement within the axon. This “dying-back” axonopathy is microscopically characterized by degeneration of axons starting at or near synapses and proceeding toward the neuronal cell body. The most distal axonal projections are furthest from the cell body and thus cannot be maintained. Thus they are most vulnerable to functional alterations; however, it is unclear whether this degeneration is caused by energy deficits, lack of antioxidants, or physical obstruction of axoplasmic flow. Axonal degeneration is followed by secondary demyelination.

Certain types of toxic and biochemical injury to axons result in a stereotypic pattern of morphologic change that affects either distal or proximal segments of the axon and results in the formation of segmental axonal spheroids. Based on the location of the spheroids, such diseases are divided into one of two groups, either diseases affecting axons a distance away from their cell bodies (distal axonopathies) or diseases affecting axons near their cell bodies (proximal axonopathies).

It is hypothesized that axonal spheroid formation and subsequent axonal degeneration are caused by alterations in axoplasmic flow, by alterations of anterograde or retrograde flow depending on the nature of the injury resulting in the accumulation and/or rearrangement of cytoskeletal proteins. The histologic lesion common to these two types of axonopathies is the formation of axonal spheroids with subsequent degeneration of the axon and secondary demyelination, a process that in many ways resembles the lesions described for Wallerian degeneration. Axonal spheroids are common to a variety of neuronal derangements; therefore distal and proximal axonopathies must be differentiated from other diseases that cause spheroids, such as the compressive axonopathies.

Distal and proximal axonopathies have been further subdivided by some scientific disciplines into groups based on whether initial axonal lesions progress in an anterograde or retrograde direction. The terminology and classification schemes, although useful to some, are outside the scope of this chapter and are often confusing. The occurrence of secondary anterograde or retrograde lesions will be discussed in the context of some of the diseases presented next.

### 14.1.2.3.3.1.1

#### Organophosphates

Organophosphates are divided into two groups according to their use, mode of action, and type of toxicity. The first group, organophosphate esters, used as pesticides (parathion, malathion, diazinon, carbaryl, aldicarb), fungicides, herbicides, or rodenticides, cause acute toxicity by inhibiting cholinesterase either directly or indirectly, allowing acetylcholine to accumulate at synaptic (nerve-nerve junctions) or myoneural junctions (nerve-muscle junctions), resulting in persistent

## Pathologic Basis of Veterinary Disease, 4th Edition

---

depolarization. In acute organophosphate toxicosis, clinical effects vary but are manifested in the following:

1. Parasympathetic nervous system, leading to salivation, lacrimation, urination, defecation, bradycardia, and pupillary constriction
2. Skeletal muscular system, resulting in muscle fasciculations followed by weakness and muscle paralysis (i.e., death is due primarily to respiratory failure)
3. Central nervous system, leading to anxiety, restlessness, hyperactivity, anorexia, and generalized seizures (i.e., observed in dogs and cats, but are uncommon in cattle)

914

Gross and microscopic lesions in the nervous system are absent, and those in other tissues are nonspecific.

915

The second group causes chronic toxicosis and is the most common cause of chemically induced distal axonopathy in veterinary medicine. This group of organophosphates includes the cresyl and related compounds, such as triorthocresyl phosphate used in hydraulic fluids, lubricants, flame-retardants, and plasticizers. The triaryl phosphate group of compounds used as high-temperature lubricants is toxic for several species of animals and human beings.

Chronic exposure (delayed neuropathy) to certain organophosphate pesticides and herbicides (trichlorphon, merphos, triorthocresyl phosphate, leptophos, parathion, malathion, diazinon) causes delayed neurotoxicity unrelated to cholinesterase inhibition as seen in acute organophosphate toxicosis. The type of axonal injury caused by these chemicals follows the stereotypic process of morphologic changes described previously and occurs approximately 10 to 14 days following exposure. Organophosphorus compounds causing delayed neurotoxicity inhibit the activity of an enzyme referred to as neuropathy target esterase. The function of the enzyme in the PNS and CNS is not fully understood.

Phosphorylation of the enzyme by the toxic compound is proposed to interfere with its normal function, resulting in axonal injury. Other studies have shown that organophosphates causing delayed neurotoxicity interact with  $\text{Ca}^{2+}$  or calmodulin kinase II, an enzyme responsible for phosphorylation of cytoskeletal proteins, such as microtubules, neurofilaments, and microtubule-associated protein-2, resulting in disassembly and accumulation of these proteins in the distal portions of axons, producing axonal swelling and degeneration.

No specific gross lesions are present in chemically induced distal axonopathies. Microscopically, there is retrograde degeneration beginning in the distal part of axons, especially those with a larger diameter. Affected areas in the spinal cord include dorsal funiculi, spinocerebellar tracts in lateral funiculi, and ventromedial aspects of the ventral funiculi. Central chromatolysis of cell bodies of affected nerves has occurred.

Clinically, signs of toxicity are usually delayed 1 to 2 weeks after exposure. Young animals, because of their ability to compensate for the neurologic deficits, tend to be less seriously affected, whereas recovery is slow and incomplete in adults. Susceptible animals include cats, domestic and exotic ruminants, chickens, pheasants, and ducks. Small laboratory animals, dogs, and some nonhuman primates are less sensitive. Clinical signs are those of combined sensory and motor neuropathy and spinal cord damage, such as proprioceptive deficits expected by damage to the spinocerebellar nucleus and tract as well as the fasciculus gracilis.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

14.1.2.3.3.1.2

### Selenium

An acute paralytic syndrome termed bilateral poliomyelomalacia has been observed in feeder pigs associated with the inadvertent inclusion of toxic amounts of selenium (selenium-enriched yeast, sodium selenite, or sodium selenate) in pig rations. The pathogenesis of the lesions is not proven but could involve an induced nicotinamide or niacin deficiency. Experimentally, 6-aminonicotinamide, a gliotoxin and antagonist of the vitamin, causes lesions analogous to those seen in the natural porcine disease.

Grossly, bilateral (symmetric) areas of softening and yellow discoloration occur in the ventral spinal gray matter of the cervical and lumbar intumescences. Microscopically, acute lesions consist progressively of neuronal chromatolysis, neuronal necrosis, neuronal loss, microcavitation, and glial necrosis. As would be expected, these changes are subsequently followed by astrogliosis and the accumulation of gitter cells. Prominent capillaries are typical. Wallerian degeneration occurs in ventral spinal nerve rootlets of those cord segments whose ventral gray horn motor neurons have been destroyed. Identical lesions have been observed in the brain stem.

Clinically, affected pigs are alert, rest in sternal recumbency, and squeal loudly when disturbed. They eventually progress to quadriplegia with flaccid paralysis of the rear limbs. Cutaneous manifestations of the toxicity also occur and include rough hair coats, partial alopecia, and separation and sloughing of the hoofs. Historically, a similar ovine bilateral symmetric poliomyelomalacia has been reported from Africa, but an association with selenium toxicity was not made.

14.1.2.3.3.1.3

### Sodium chloride

Sodium chloride toxicity, also known as sodium ion toxicosis, water deprivation syndrome, or salt poisoning, occurs primarily in pigs, poultry, and occasionally in ruminants, dogs, horses, and sheep. The disease occurs following over-consumption of sodium chloride in rations or supplements and can be complicated by limited availability of drinking water, resulting in severe dehydration. A similar sequence of events can occur with simple water restriction of sufficient duration to allow compensation by the brain's adaptive response to chronic hypernatremia (hyperosmolarity). Sodium chloride toxicity is due to hyperosmolarity (hypernatremia) caused by excessive intake of sodium salts or severe dehydration followed by rehydration and a "rapid" hypernatremic to normonatremic or hyponatremic shift.

During the initial hypernatremic phase, the brain "shrinks" because of the osmotic loss of water. An influx of sodium, potassium, and chloride ions into the brain, beginning within minutes after the osmotic loss of water, is an acute adaptive response to equalize the sodium imbalance. Maintenance of a normal ionic balance in the brain is critical, however, for normal function and, although a new ionic equilibrium is established, this acute response alone cannot compensate for severe or prolonged hypernatremia.

A second, more delayed adaptive response of the brain is an influx or endogenous production of organic osmolytes, such as certain amino acids, polyols, and methylamines, to equalize the osmotic imbalance created by hypernatremia. This response requires hours or days to establish a new osmotic equilibrium. When animals are given free access to fresh water, an acute hypernatremic to

915

916

## Pathologic Basis of Veterinary Disease, 4th Edition

---

hyponatremic shift occurs. Within minutes, the brain attempts to offset this osmotic imbalance by eliminating sodium, potassium, and chloride ions by actively transporting these ions into the vasculature. This early response cannot, however, offset the osmotic stress created by the increased organic osmolytes in the brain. As a result of the osmotic gradient created by the elevated organic osmolytes, water enters the brain with subsequent brain swelling.

Grossly, lesions are inconsistent but include cerebral and leptomeningeal congestion and edema. Zones of cerebrocortical laminar necrosis can be detected in transverse slices of fixed brain. Microscopically, cerebrocortical neuronal necrosis, often laminar, is accompanied by astrocytic swelling. In pigs, leptomeninges and perivascular spaces can have an infiltrate of eosinophils and, with longer survival, an influx of macrophages occurs depending on the extent of necrosis. The leptomeningeal and perivascular infiltrate of eosinophils is an inconsistent finding. Pallor of subcortical white matter is indicative of edema, and prominence of small cortical blood vessels is due to congestion and swelling of endothelial cell nuclei. In ruminants, arteriolar degeneration with a transmural neutrophilic infiltrate, cerebellar Purkinje cell necrosis, and edema of basal nuclei, thalamus, and midbrain have been observed.

Clinical signs include inappetence and dehydration early followed by heading pressing, incoordination, blindness, circling, paddling, and convulsions. Animals are often found dead in their pasture or pen.

14.1.2.3.3.2

### Metals

14.1.2.3.3.2.1

#### Arsenic

Toxicity due to ingestion or cutaneous absorption can occur with inorganic and organic arsenicals and can affect multiple organs including the nervous system. Inorganic compounds are predominantly herbicides or pesticides, whereas organic arsenicals (arsanilic acid, 3-nitro-4-phenylarsonic acid) have been used as feed additives in the pig and poultry industries as growth promoters and to control enteric diseases.

Poisoning with inorganic arsenicals is an acute enteric disease with hepatic and renal manifestations, but neurologic signs can occur. Probably because of the nature of the organic compounds and the manner of their use, there is greater potential for neurotoxicity. Arsanilic acid has a greater tendency to cause peripheral and optic nerve and tract damage, whereas 3-nitro compounds tend to affect the spinal cord more severely.

Gross lesions are not present. Microscopically, lesions in cranial and peripheral nerves and spinal cord consist of axonal degeneration and fragmentation of myelin sheaths. In the spinal cord following 3-nitro poisoning, lesions are found chronologically in the cervical and thoracic cord followed by lesions in the lumbar cord. Spinocerebellar tracts and dorsal funiculi are predominantly affected. The distribution of lesions suggests that the distal segments of long ascending fiber tracts can be preferentially injured. Inorganic arsenicals inhibit sulfhydryl enzyme systems and disrupt cellular metabolism. The exact mode of action of organic arsenicals is unknown.

In pigs, clinical signs include blindness resulting from damage to optic nerves and tracts and incoordination, paresis, and paralysis related to spinal cord and peripheral nerve lesions.

### Lead

Lead poisoning has occurred in a variety of animals, but with the increased awareness of the potential for toxicity and environmental contamination and current regulations, such as reduced concentrations in paint and unleaded gasoline, poisoning is uncommon and if it occurs is most common in cattle. Potential sources include discarded car batteries and old flaking or peeling lead paint in barns and farm buildings.

Depending on the quantity absorbed, poisoning can be peracute with no gross or microscopic lesions, acute, subacute, or chronic. In peracute or acute cases, contents of the upper digestive tract, such as fragments of battery plates or flakes of paint, could indicate the possibility of lead poisoning. Lead poisoning can affect many tissues and organs, including CNS, PNS, liver, kidneys, gastrointestinal tract, bone marrow, blood vessels, and organs of the reproductive and endocrine systems. In horses grazing lead-contaminated pastures, a cranial neuropathy with laryngeal and facial paralysis has been described.

Lead poisoning in cattle and other species is via the oral route or, less commonly, via the respiratory system or skin (inorganic lead). Lead can damage the brain through a variety of mechanisms. Direct toxic effects on neurons, astrocytes, and cerebral endothelial cells occur by disrupting metabolic pathways and altering the function of dopaminergic, cholinergic, and glutamatergic neurotransmitter systems. Lead crosses the blood-brain barrier rapidly using a cationic transporter, concentrates in the brain because of its ability to substitute for calcium ions in the pump, and enters astrocytes and neurons by voltage-sensitive cell membrane calcium channels. Lead disrupts calcium homeostasis, causing the accumulation of calcium in lead-exposed cells, and induces mitochondrial release of calcium, leading to apoptotic cell death. Astrocytes contain metallothionein and can sequester potentially toxic metals in the CNS, thus protecting more vulnerable neurons from the toxic effects of lead. However, astrocytes may also be sensitive to the toxic effects of lead, leading to functional deficits such as in the uptake, transport, and metabolism of neurotransmitters. Transplacental (human beings and sheep) and neonatal lead exposure can result in delayed brain maturation and biochemical abnormalities.

916

917

Gross lesions in the CNS are usually absent. When present, they can resemble those present in polioencephalomalacia of cattle, but this is uncommon. In general, gross lesions, if present, are distributed in a laminar pattern and include meningeal and cerebrovascular congestion, brain swelling with flattening of gyri, or hemorrhage. With longer survival times, there may be foci of cerebrocortical malacia (softening), cavitation, and laminar necrosis followed by cerebral cortical atrophy, widened sulci, narrowed gyri, and loss of white matter.

Microscopically, lesions in peracute cases are absent. In acute cases, congestion, astrocytic swelling, status spongiosis, and microvascular prominence caused by endothelial hypertrophy are present, and often ischemic neuronal cell change is characteristically confined to the tips of cerebrocortical gyri. For most cases in cattle, only a few necrotic neurons at gyral tips and minimal astrocytic swelling, vascular prominence, and congestion can be found. With longer survival times, cerebrocortical lesions progress to laminar necrosis, accumulations of macrophages, or liquefactive necrosis, the last being rare. Because of their similarities, lesions of lead encephalopathy in ruminants must be differentiated from those of thiamine deficiency-induced polioencephalomalacia and sulfur-related polioencephalomalacia.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Lesions in dogs resemble those in cattle, but vascular damage is more obvious and consistent. Vascular lesions can progress to mural hyalinization, necrosis, and thrombosis. Other lesions include neuronal necrosis in the cerebral cortex, hippocampus, and cerebellum (Purkinje cells), myelin destruction in cerebrocortical white matter, and a peripheral neuropathy.

Clinically, affected cows are often found down or dead in the pasture. If clinical signs are present, they range initially from depression, inappetence, and diarrhea to teeth grinding (bruxism), circling, head pressing, incoordination, and blindness later. In small animals, especially dogs, clinical signs include ataxia, tremors, clonic-tonic seizures, blindness, and deafness.

14.1.2.3.3.2.3

### Organotins

Excessive exposure to organotins such as triethyltin (stabilizer, catalyst, wood and textile preservative, fungicide, bactericide, and insecticide) causes cytotoxic edema principally affecting myelin sheaths of oligodendroglial cells in the white matter. Experimental studies have shown that triethyltin selectively damages myelin sheaths and causes a decrease in potassium concentrations in the white matter with a concurrent increase in intracellular water content. The blood-brain barrier is not affected. The mechanism of injury is thought to be uncoupling of oxidative phosphorylation and inhibition of mitochondrial ATPase activity within cell membranes. Loss of Na/K-dependent ATPase activity in cell membranes of myelin lamellae leads to the formation of intramyelinic edema.

Gross lesions, if present, consist of an enlarged brain and spinal cord. Because of compression against the cranium, an affected brain has flattened gyri and shallow indistinct sulci.

Microscopically, fluid accumulates between myelin layers and leads to splitting of the myelin lamellae and the formation of intramyelinic spaces.

14.1.2.3.3.3

### Microbial Toxins

14.1.2.3.3.3.1

#### Botulism

See Peripheral Nervous System.

14.1.2.3.3.3.2

#### *Clostridium perfringens* type D encephalopathy (pulpy kidney disease, overeating disease)

*Clostridium perfringens* type D enterotoxemia, associated with epsilon toxin production, is a disease of sheep, goats, and cattle, but only sheep commonly exhibit the neurologic manifestations of the disease. Brain damage is due to vascular injury and breakdown of the blood-brain barrier. Binding of epsilon toxin to endothelial cell surface receptors results in opening of tight junctions, disturbed transport processes, increased vascular permeability that results in vasogenic edema, swelling of astrocytic foot processes, and ultimately necrosis caused by hypoxic-ischemic mechanisms. Some of the effects of epsilon toxin can be mediated by an adenyl cyclase-cAMP system.

Gross lesions are absent in some peracute cases but, when present, consist initially of bilaterally symmetric foci of malacia, leading to yellow-gray to red foci with malacia and cavitation (Fig. 14-77). Lesions can be found in the internal capsule, basal nuclei, thalamus, hippocampus, rostral colliculus and substantia nigra, pons, corona radiata of frontal cortex, and cerebellar peduncles,

917

918

## Pathologic Basis of Veterinary Disease, 4th Edition

especially the middle peduncle. Lesions in other tissue consist of pulmonary congestion and edema, serous pericardial effusion, petechiation, and soft (pulpy) kidneys.

**Fig. 14-77 Focal symmetric encephalomalacia, brain, transverse section at the level of the basal nuclei and rostral thalamus, sheep. A,** There are bilateral discoloration and malacia (*arrows*) in a portion of the basal nuclei. These lesions are caused by an enterotoxin produced by *Clostridium perfringens* type D. **B,** Microscopically the walls of arterioles can be hyalinized, and endothelial cell nuclei swollen and vesicular (not shown here) with perivascular laking of proteinaceous fluid. Pericapillary hemorrhage and acute necrosis of neurons and macroglia can occur. With longer survival, as seen here, lesions include destruction of neuropil, accumulation of neutrophils and foamy macrophages (*gitter cells*—*left half of the figure*), and lymphocytic perivascular cuffing. In this case, the inflammatory response is pronounced and would not be considered typical of this disease. H&E stain. (**A,** Courtesy Dr. D. Cho, College of Veterinary Medicine, Louisiana State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B,** Courtesy Dr. J. Simon, College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Microscopically the CNS lesion in acute cases is vasogenic edema secondary to vascular injury. The fluid in perivascular spaces is frequently protein rich and eosinophilic. Walls of arterioles can be hyalinized, and endothelial cell nuclei swollen and vesicular. Vasogenic edema, which is interstitial in location, gives a light or pink-staining, spongy appearance to the CNS parenchyma. Both gray matter and white matter are affected. Pericapillary hemorrhage and acute necrosis of neurons and macroglia occur. Other changes occur with longer survival and include axonal swelling, accumulation of neutrophils and foamy macrophages, vascular prominence caused by perithelial-endothelial nuclear enlargement or swelling, lymphocytic perivascular cuffing, and liquefactive necrosis.

Sheep of all ages, except newborns, are susceptible; incidence peaks between 3 and 10 weeks of age and in feeder lambs shortly after arrival at a feedlot. Resistance of newborns can be related to lack in the gut of pancreatic proteolytic enzymes necessary for activation of the epsilon toxin, and to trypsin inhibitors in colostrum. Lambs are typically in good condition and are found dead.

14.1.2.3.3.3

### Edema disease (enterotoxemic colibacillosis)

Edema disease is a disorder of rapidly growing, healthy feeder pigs being fed a high-energy ration. The disease is caused by strains of *Escherichia coli* producing a Shiga-like toxin, which is similar to toxins produced by *Shigella dysenteriae* and is designated Shiga-like toxin type IIe (SLT-IIe). This toxin causes necrosis of smooth muscle cells in small arteries and arterioles and a reduction focally in the degree of circulation to the CNS parenchyma, leading to infarction manifested grossly as malacia in the CNS. Glycolipid cell surface receptors on endothelial cells, globotriaosylceramide or globotetraosylceramide, are binding sites for the toxin, and their presence confers susceptibility to the disease. Binding of the toxin to these receptors can initiate a chain of inflammatory and immunologic reactions that lead to vascular damage.

The basic lesion is an angiopathy that leads to edematous and hypoxic-ischemic injury in a variety of tissue, including the brain. Grossly, edema is present in the subcutis often prominent in the palpebrae, cardiac region of the gastric submucosa, gallbladder, colonic mesentery, mesenteric lymph nodes, larynx, and lungs, and serous effusions occur in the thoracic cavity and pericardial sac. Congestion, and sometimes hemorrhage, also occur. The characteristic gross lesions in the brain are usually bilaterally symmetric foci of necrosis in the caudal medulla, but they can extend rostrally as far as the basal nuclei. The lesions are yellow-gray, soft, and slightly depressed.

The primary microscopic lesion, a degenerative angiopathy/vasculitis, is noted most frequently and is most severe in the caudal medulla to the diencephalon and in cerebral and cerebellar meninges.

918

919

Cerebral, cerebellar, and spinal blood vessels are also affected. Initially, perivascular edema results from early vascular injury. Edema is followed by necrosis of medial smooth muscle cells, deposition of fibrinoid material, and accumulation of macrophages and lymphocytes in the adventitia. Although endothelial cells and their nuclei become swollen and vesicular, this layer generally remains intact, and consequently thrombosis is not a feature. Lesions associated with the angiopathy include pallor and spongiosis of the CNS parenchyma caused by vasogenic edema and necrosis of neurons and glia. An influx of macrophages into the necrotic lesions can be observed with longer survival times.

Pigs are usually 4 to 8 weeks of age, but younger and older pigs can be affected. Clinically, affected animals are initially ataxic and then become laterally recumbent with rhythmic paddling of the limbs. As the disease progresses, they may become comatose and die. Most pigs die within 24 hours;

## Pathologic Basis of Veterinary Disease, 4th Edition

---

however, pigs that survive for several days typically develop CNS lesions (see chronologic sequence of infarction, [Table 14-1](#)).

14.1.2.3.3.4

### Leukoencephalomalacia

Ingestion of moldy feed, mainly corn or corn by-products, contaminated with the fungus *Fusarium moniliforme* causes an acute fatal neurologic disease in horses called leukoencephalomalacia. The primary toxin isolated from *Fusarium moniliforme* has been named fumonisin B<sub>1</sub>, although other fumonisins have been extracted. The exact mechanism of injury has not been fully defined. Based on the character and progression of lesions, vascular damage has been inferred as the primary injury. Although unproven, the gross lesion is thought to be an infarct by some pathologists. Fumonisin disrupts cellular membranes, is associated with lipid peroxidation of cells and cellular membranes, inhibits synthesis of macromolecules and DNA, and may enhance production of TNF- $\alpha$  by macrophages. Also, fumonisins inhibit the enzyme ceramide synthase, interfering with the synthesis of sphingolipids. Sphingolipids are bioactive compounds that participate in the regulation of cell growth, cell differentiation, cell metabolic functions, and apoptotic cell death.

Gross lesions involve the white matter of the frontal and parietal lobes of the cerebral hemispheres most commonly, but cases with involvement of major white matter tracts in the brain stem and deep cerebellar white matter have occurred ([Fig. 14-78](#)). As a result of the white matter damage, including edema, brain swelling is marked with flattening of cerebrocortical gyri. The lesions are often bilateral but not symmetric, are unequal in severity, and can be quite extensive. The characteristic gross lesion at the time of death is yellow gelatinous malacia and liquefaction of the affected white matter due predominately to the breakdown of lipids accompanied by hemorrhage. The reason white matter, including subcortical white matter, is principally involved—whereas the cerebral cortical gray matter is spared—is thought to be related to a unique vulnerability of the blood vessels in the white matter. The mechanism for this selective vulnerability is unknown.

Microscopically the affected white matter is coagulated or liquefied, and the neuropil is disrupted by accumulation of pink-staining proteinaceous fluid with scattered neutrophils and macrophages. The border of the lesion is surrounded by diffuse or perivascular edema, perivascular hemorrhage, and blood vessels with small leukocytic cuffs. Blood vessel walls are degenerate or necrotic, and some are infiltrated with neutrophils, plasma cells, and eosinophils. Although not often detected, thrombosis occurs. Less characteristic changes include edema and perivascular cuffing in the leptomeninges and neuronal necrosis in deeper layers or the entire width of the overlying gray matter. Similar lesions have been reported in the spinal cord where gray matter is preferentially affected.

Leukoencephalomalacia can also be associated with hepatotoxicity, or hepatotoxicity can be the sole manifestation. Additionally, other animals including pigs, ducks, and chickens are susceptible, but clinical disease and lesions generally reflect pulmonary, hepatic, or renal injury. Clinical signs can include depression, somnolence, head pressing, aimless wandering, blindness, or seizures. Rapid progression of these clinical signs followed by death is typical ranging from 1 to 10 days after onset.

14.1.2.3.3.5

### Tetanus

Tetanus is a spastic paralytic disease caused by the neurotoxin called tetanospasmin produced by *Clostridium tetani*. Similar to *Clostridium botulinum*, the bacterium is a ubiquitous gram-positive

## Pathologic Basis of Veterinary Disease, 4th Edition

spore-forming anaerobe commonly found in soil. Tetanospasmin is synthesized in anaerobic wounds and first binds at myoneural junctions and/or sensory receptors. It is transported via retrograde axoplasmic flow within the axon and across synaptic junctions until it reaches the CNS. In the CNS, the toxin is transferred across synapses until it becomes fixed to gangliosides in the presynaptic inhibitory motor neuron. Tetanospasmin blocks the release of inhibitory neurotransmitters, such as glycine and GABA. Inhibitory neurotransmitters act to dampen the actions of excitatory nerve impulses from upper motor neurons that are imposed on lower motor neurons. If these impulses cannot be dampened by normal inhibitory mechanisms, the generalized muscular spasms characteristic of tetanus ensue. Tetanospasmin appears to act by selective cleavage of a protein component of synaptic vesicles, thus preventing the release of neurotransmitters by the cells. Once toxin is bound to synapses, the administration of antitoxin is useless.

919

920

**Fig. 14-78 Leukoencephalomalacia, horse, brain.** **A**, Sagittal section. The white matter of the frontal and parietal lobes is necrotic (malacia). The gray matter is not affected. This disease is caused by the toxin fumonisin B<sub>1</sub> produced by the fungus *Fusarium moniliforme* that grows in damaged feed grains. Note that this case demonstrates the extent and distribution of liquefactive necrosis in the white matter in this disease. A more typical presentation is shown in [Fig. 14-78, B](#). **B**, Transverse section. The white matter of the three cerebral gyri located at the top of the illustration has areas of yellow gelatinous softening and hemorrhage. Because of the absence of cavitation (liquefactive necrosis), the age of this lesion is likely less than the lesion depicted in [Fig. 14-78, A](#). (**A**, Courtesy Dr. J. Simon, College of Veterinary Medicine, University of Illinois. **B**, Courtesy Dr. W. Crowell, College of Veterinary Medicine, University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

This disease is most common in horses but may also occur in lambs castrated in areas contaminated with spores of *Clostridium tetani*. Tetanus also has been reported in cows, pigs, dogs, and cats. Except for the anaerobic wound, there are no macroscopic and microscopic tissue lesions in tetanus. Infected horses initially show signs of colic and muscle stiffness involving muscle groups of the lips, nostrils, ears, jaw (lockjaw), and tail. Horses are hyperesthetic and rapidly have a spastic and tetanic paralytic syndrome develop.

14.1.2.3.3.4

### Plant Toxins

14.1.2.3.3.4.1

#### *Astragalus*, *Oxytropis*, and *Swainsona* poisoning

*Astragalus*, *Oxytropis*, and *Swainsona* represent three genera of plants with species that are toxic to livestock. As many as 300 species of *Astragalus* grow in North America, and the genus is the largest of any legume family in this part of the world. Three categories of toxicity can be observed with *Astragalus*, depending on the mechanism or manner of toxicity: nitro-containing, selenium-accumulating, and poisoning of the locoweed type. Only the last is discussed here. Locoweed poisoning, or locoism, is associated with ingestion of certain species of *Astragalus* and *Oxytropis* in North America and *Swainsona* in Australia. The toxic principles have been termed locoine and swainsonine, respectively.

The mechanism of toxicity has been clarified by the isolation of the indolizidine alkaloids swainsonine and swainsonine N-oxide from *Astragalus lentiginosus*. Both compounds inhibit lysosomal  $\alpha$ -mannosidase, thus inducing an acquired  $\alpha$ -mannosidosis that mimics the inherited storage disease mannosidosis. Mannosidases are glycoside-hydrolyzing enzymes that are found in the Golgi, lysosomes, and cytoplasm of all mammalian cells. Analyses of tissue from animals poisoned with swainsonine have shown that swainsonine is present in all tissue; however, neurons, epithelial cells in organ systems such as the liver, and macrophages of the monocyte-macrophage system of the spleen and lymph nodes are commonly affected. Therefore, just like in the inherited storage disease (like mannosidosis), acquired swainsonine-induced storage diseases affect similar cells throughout the body. Additionally, swainsonine interferes with normal synthesis of glycoproteins containing asparagine-linked complex oligosaccharides. Swainsonine also inhibits Golgi mannosidase II, an effect not recognized in the inherited disorder.

920

921

There are no specific gross lesions in acquired swainsonine-induced storage diseases. Microscopically, lesions involve neuronal cell bodies throughout the neuraxis and autonomic ganglia and are analogous to the inherited lysosomal storage diseases.

Microscopically, neuron cell bodies are swollen and nuclei are sometimes displaced to the periphery of the cell body. The cytoplasm appears foamy or finely vacuolated. The material that accumulates in the cytoplasm does not stain for lipid. Irregular fusiform enlargements, called meganeurites, occur in the proximal axon segment and aberrant synapses form. With time, lesions include distal axonal degeneration and neuronal necrosis with mineralization. The presence of cytoplasmic lesions in other cells of the CNS, such as astrocytes, is dependent on the degree to which  $\alpha$ -mannosidase is expressed in individual cell populations. Astrocytes are hydropic or swollen, but their appearance is less dramatic and diagnostic when compared with changes in neurons. Macrophages recruited from the blood stream to phagocytose debris and mannose released from dead neurons also are affected by swainsonine. Microgliosis and neuronophagia are present but inconspicuous.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Similar to the swelling and vacuolation of neurons, this process also occurs in cells throughout the body, including hepatocytes, exocrine pancreatic cells, renal tubular epithelium, endocrine organs (thyroid, parathyroid, and adrenal glands), circulating leukocytes, and cells of the monocyte-macrophage system in liver, spleen, and lymph nodes. Ingestion of the plants of these species by females during gestation can also result in abortion or birth of weak neonates that have similar lesions.

Cattle, sheep, and horses are generally affected. Toxicity is usually insidious, and clinical signs are not observed until after the plants have been grazed on for 14 to 60 days. Clinical signs include poor condition, depression, head pressing, incoordination, circling, blindness, recumbency, and paddling.

### 14.1.2.3.3.4.2

#### *Centaurea* spp. poisoning

Horses grazing *Centaurea solstitialis* (yellow star thistle) or *Centaurea repens* (Russian knapweed) have a disorder develop known as nigropallidal encephalomalacia. This disease is similar to Parkinson's disease in human beings and has been proposed as a model for experimental studies. The specific cause of the syndrome is not proven. A sesquiterpene lactone isolated from *Centaurea repens* termed repin could provide a basis for the neurotoxicity. Cytotoxicity in cell culture was associated with depletion of glutathione (a major antioxidant), an increase in reactive oxygen species, and evidence of membrane damage in PC12 cells (a pheochromocytoma cell line) and mouse astrocytes. High concentrations of monoamine oxidase involved in dopamine metabolism normally found in the dopaminergic striatonigral tract (i.e., striatum and substantia nigra [regulate balance and movement]) could render these areas of the brain more susceptible to oxidative damage caused by repin. The mechanism by which repin might cause an increased oxidative state with glutathione depletion, free radical production, and damage to cellular membranes is unknown. Repin is also reported to inhibit dopamine release in the rat striatum, potentially contributing to the clinical manifestations of the disorder. Other potential toxins isolated from *Centaurea solstitialis* include the excitotoxic amino acids aspartate and glutamate. It is unlikely that these amino acids are involved in the naturally occurring disease.

Gross brain lesions are sharply demarcated foci of yellow discoloration and malacia in the globus pallidus (pallidal) and substantia nigra (nigro) (Fig. 14-79). Lesions are usually bilateral and vary in severity; however, unilateral lesions also occur. Microscopically, necrosis with loss of neurons is the primary lesion; however, axons, glia, and blood vessels also are necrotic. The debris is phagocytosed by macrophages (monocytes) recruited into the lesion from the blood stream.

Fig. 14-79 Equine nigropallidal encephalomalacia, brain, transverse section through the midbrain at the level of the rostral colliculi, horse. This lesion is caused by yellow star thistle poisoning. Note the symmetrically cavitated (malacia) lesions in the substantia nigra (*arrows*), resulting from necrosis and phagocytosis by gitter cells. (Courtesy Dr. L. Lowenstine, School of Veterinary Medicine, University of California-Davis; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

921

Grazing the plants for 1 month or longer during the hot summer months when other forage is dried and unpalatable can cause clinical disease. Affected horses are somnolent, have persistent chewing movements, and have difficulty in prehension of feed and drinking water. Death generally is due to emaciation and starvation.

922

### 14.1.2.3.4 MISCELLANEOUS

#### 14.1.2.3.4.1 Cholesteatomas

Cholesteatomas, also called cholesterol granulomas, form in choroid plexuses of the ventricles in horses as an aging change. These masses are usually incidental, but reports suggest that if they grow large enough and occlude the flow of CSF, acquired hydrocephalus can result. Cholesteatomas are tan to yellow-brown firm masses with a smooth to, in some cases, papilliform surface (Fig. 14-80). Occasionally the masses are mineralized. This lesion is thought to result from edema and minor but

## Pathologic Basis of Veterinary Disease, 4th Edition

---

repeated hemorrhages within the choroid plexuses, which result in cholesterol deposits. These deposits elicit a foreign body inflammatory reaction (foreign body granuloma) in the choroid plexus.

14.1.2.3.4.2

### Dural Ossification

Dural ossification (ossifying pachymeningitis and dural metaplasia) is a metaplastic aging change in dogs, particularly the large breeds. The dura of the cervical and lumbar enlargements of the spinal cord, usually on the ventral and ventrolateral aspects, have well-differentiated bone that can form bone marrow, giving this bone a red color (Fig. 14-81). Thoracolumbar pain in affected dogs is thought to arise following flexion/extension of the spinal column as a result of compression of spinal roots as they penetrate the metaplastic dura.

**Fig. 14-80 Cholesterol granuloma (cholesteatoma), brain, sagittal section, horse.** The choroid plexus of the lateral ventricle contains an expansile mass consisting chiefly of cholesterol and a granulomatous inflammatory response (*arrow*). (Courtesy College of Veterinary Medicine, University of Illinois.)

Fig. 14-81 **Osseous metaplasia, dura mater, dog.** Also called ossifying pachymeningitis and dural ossification, the dura mater contains well-differentiated bone and bone marrow (*arrows*). With movement of the vertebrae, the metaplastic bone can impinge on nerve roots and cause pain in large breed dogs. (*Courtesy College of Veterinary Medicine, University of Illinois.*)

14.1.2.3.4.3

### Inherited Necrotizing Myelopathy of Afghan Hounds

Inherited necrotizing myelopathy of Afghan hounds seems to have an autosomal recessive inheritance. The lesions are similar to subacute combined degeneration of the spinal cord due to vitamin B<sub>12</sub> deficiency in human beings and primates, but B vitamin status in affected dogs is considered normal. A similar disease has been reported in Dutch Kooiker dogs, but the relative degrees of axonal degeneration versus demyelination have not been adequately described.

Topographically, gross lesions in the cervical cord are in ventral and less commonly dorsal funiculi, all funiculi in the thoracic cord, and ventral funiculi in lumbar areas. In well-developed lesions, there is severe destruction of the spinal white matter, with an influx of macrophages and myelin degradation that progresses to microcavitation. Neuronal cell bodies in spinal gray matter and ventral nerve rootlets are unaffected. Necrosis, perivascular accumulations of macrophages, and astrogliosis in the dorsal nucleus of the trapezoid body are variable.

Clinical signs begin between 3 and 13 months of age and progress rapidly to paraplegia or tetraplegia within 1 to 3 weeks.

14.1.2.3.4.4

### Leptomeningeal Fibrosis

Aging dogs will have varying degrees of leptomeningeal fibrosis involving the recesses of the cerebral sulci (Fig. 14-82). This lesion is not present in the leptomeninges covering the outermost surfaces of the gyri. This latter feature can be useful in differentiating meningeal fibrosis from suppurative meningitis. Except for mild meningitis, exudates will also accumulate within the leptomeninges on the outermost surfaces of the gyri.

922

923

**Fig. 14-82 Meningeal fibrosis, leptomeninges (pia-arachnoid mater), dog.** In old dogs, the leptomeninges can have areas of fibrosis (*white areas*) particularly in the sulci. This lesion must not be confused with acute leptomeningitis and accumulation of exudate in the leptomeninges and subarachnoid space. In the latter, the exudate extends into the sulci and also covers the gyri (see [Fig. 14-47, A](#)). (Courtesy College of Veterinary Medicine, University of Illinois.)

14.1.2.3.4.5

### Meningeal Melanosis (Congenital)

The leptomeninges of animals and human beings with heavily pigmented skin, especially black-faced sheep and black-skinned pigs, can have melanin ([Fig. 14-83](#)). The extent and degree of pigment deposition varies dramatically from animal to animal. Similar pigment deposits can be found in other areas of the body, including the lung, uterine caruncles, liver, and respiratory and alimentary systems' mucous membranes. Congenital meningeal melanosis produces no clinical impairment in affected animals.

14.1.2.3.4.6

### Reticulosis/Granulomatous Meningoencephalitis

Reticulosis has been reported to occur in several species but is most common in the dog. The term *reticulosis*, at best a somewhat imprecise designation, is used here to give a historical perspective. The spectrum of lesions originally included three disease processes: inflammatory (granulomatous meningoencephalitis) reticulosis, neoplastic reticulosis, and microgliomatosis (proliferation of microglia). Some pathologists have considered the inflammatory and neoplastic forms of reticulosis to represent two opposing ends of a spectrum, with intermediate or transitional forms falling in between. Microgliomatosis is considered to be distinct from the other two types. Recently an additional designation, granulomatous meningoencephalomyelitis, has been used to describe a process that is considered to be analogous, at least in some instances, to the inflammatory form of reticulosis. Ophthalmic lesions also accompany this form and involve the optic nerve, optic disk, and retina.

**Fig. 14-83 Melanosis, leptomeninges (pia-arachnoid mater), sheep.** Note the black pigmentation of the leptomeninges overlying the olfactory poles and dorsal aspect of the frontal lobe. Meningeal melanosis is a normal finding in black-faced sheep and other animals with heavily pigmented skin. (Courtesy Dr. D. Morton, College of Veterinary Medicine, University of Illinois.)

When present, gross lesions of the three forms are rarely discrete. They frequently are gray-white to red, expansive areas within the brain, which result in a loss of structure (Fig. 14-84). However, lesions can have irregular, well-defined margins, have a gelatinous or rubbery consistency, or appear granular. Microscopically the inflammatory form of reticulosis is characterized by perivascular accumulation of well-differentiated lymphocytes, monocytes, plasma cells, and epithelioid cells with occasional occurrence of neutrophils and giant cells, plus reticulin fibers and collagen. Not infrequently, cells will be predominantly epithelioid. The inflammatory lesion has recently been characterized as consisting primarily of CD3<sup>+</sup> T lymphocytes and activated macrophages with strong MHC class II expression, which led to the suggestion that the underlying mechanism of the disease process was a T lymphocyte-mediated delayed-type hypersensitivity of an organ-specific autoimmune disease.

923

Fig. 14-84 Granulomatous meningoencephalitis (GME, also termed inflammatory reticulosis), transverse section of midbrain just rostral to the pons, dog. The mesencephalon is swollen, discolored, markedly distorted, and soft due to extensive granulomatous inflammation (*arrows*), which has displaced the midline to the right. The mesencephalic aqueduct is also compressed and distorted. (Courtesy Dr. J. Edwards, College of Veterinary Medicine, Texas A&M University; and Dr. J. King, College of Veterinary Medicine, Cornell University.)

With the neoplastic form of reticulosis, cells are arranged around vessels and are also usually present in the tissue. The cells are less differentiated than in the inflammatory form of the disease, and mitotic figures are common. Also, prominent concentrically arranged reticulin fibers are present around vessels and around neurons and glial cells in the tissue.

Reticulosis, with clinical signs of ataxia and proprioceptive deficits, appears to occur more commonly in small breeds such as poodles and terriers. Age of affected dogs is variable and ranges from 9 months to 10 years. In three separate studies involving a total of 85 dogs with reticulosis (including all three forms), the sex distribution was 56 females and 29 males.

### 14.1.2.4 CIRCULATORY DISTURBANCES

Many diseases of the CNS in veterinary medicine result from injury to the circulatory system and vascular endothelium. Vascular diseases of the CNS can result from inflammation/infection, either as a component of a systemic disease process or from extension of inflammatory meningeal or cerebral disease. The incidence of cerebrovascular diseases analogous to those in human beings, including trauma, is low in animals, and neurologic manifestations associated with these diseases are uncommon. Arteriosclerosis ("hardening" of

## Pathologic Basis of Veterinary Disease, 4th Edition

arteries) can be categorized as lipid (atherosclerosis) or nonlipid arteriosclerosis; the latter includes arterial fibrosis, mineralization, and amyloid deposition (see [Chapter 10](#)).

14.1.2.4.1

### ATHEROSCLEROSIS

Atherosclerosis is reported in a variety of animals including nonhuman primates, pigs, dogs, and several avian species. Older pigs are most commonly and severely affected. Occasional older dogs with chronic hypothyroidism or diabetes mellitus can have severe atherosclerosis. The pathogenesis of atherosclerosis and atherosclerotic plaque formation is most well understood in human beings, and the results of experimental studies may have some application to understanding atherosclerosis in domestic animals.

Atherosclerotic plaques arise from a complex and partially understood interaction among endothelium, smooth muscle cells, platelets, T lymphocytes, and monocytes. Endothelial injury induced by oxidized low-density lipoprotein [LDL] cholesterol results in vascular inflammation of the tunica intima. Monocytes migrate into the intima of the vessel wall to phagocytose LDL cholesterol. This process results in the formation of foam cells characteristic of early atherosclerosis (fatty streak). In addition, activated macrophages produce factors that also injure the endothelium. LDL cholesterol concentrations in foam cells and smooth muscle cells often exceed the antioxidant properties of normal endothelium. Oxidized LDL leads to additional metabolic changes that foster a procoagulant microenvironment and enhanced platelet-mediated thrombus formation, as well as initiates a cascade of events leading to the lesions associated with the development of mature atherosclerotic plaques (fibrous plaques with a cap [lipid-laden macrophages walled-off by connective tissue]). The location of atherosclerotic plaques in the circulatory system is dependent on fluid shear stresses and their interaction with injured vascular endothelium. Atherosclerotic plaques characteristically occur in areas of vessel branching or areas where blood undergoes a sudden change in velocity and/or direction of flow.

Although atherosclerotic plaques can reach sizes large enough to significantly reduce blood flow to regions of the brain, the stability of the plaques determines the seriousness of the disease. A stable plaque is characterized by an excess of smooth muscle cells with few lipid-containing macrophages. An unstable plaque is characterized by a large lipid-rich core with abundant lipid-containing macrophages, thin fibrous cap, and inflammation. Rupture of unstable plaques can lead to vascular thrombosis or thromboembolism and infarction of areas supplied by these vessels in the CNS.

Grossly, vessels that can be involved include the aorta and its major branches, extramural coronary arteries, renal arteries, and cerebral arteries. Affected arteries are rigid, irregularly thickened, and white to yellow-white (atheromatous plaques) ( <a href="#">Fig. 14-85</a> ). Arterial lumina are narrowed or almost obliterated, but there is usually no appreciable ulceration, thrombosis, or hemorrhage. Intimal thickening in intracranial arteries contain less lipid and have a greater tendency for fibrosclerosis than other vessels. In arteries within the brain, there is collagenous adventitial or transmural thickening. The arterial lesions can be associated with hemorrhage or infarcts involving basal nuclei, fornix, internal and external capsules, hippocampus, and thalamus.	924 925
---	------------

**Fig. 14-85 Atherosclerosis, cerebral arteries, brain, ventral surface, dog.** The basilar artery, the arteries of the circle of Willis, and the cerebral arteries are segmentally yellow, thickened, and beaded in appearance from atheroma (*arrows*). This dog had long-standing hypothyroidism. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

In the dog, lesions involve cerebral, coronary, and renal arteries and vessels elsewhere in the body and are most severe in the intima and media. Hemorrhage, ischemia, and infarction of the cerebral cortex are uncommon but can occur.

### 14.1.2.4.2

#### CEREBRAL EDEMA (PERMEABILITY CHANGES)

The causes and mechanisms of cerebral edema are presented in the section on vasogenic, cytotoxic, and interstitial edema. Cerebral edema has also been associated with “water intoxication,” which can result from an increased body hydration caused by (1) excessive, faulty intravenous hydration; (2) compulsive drinking caused by abnormal mental function; or (3) altered antidiuretic hormone secretion. The increased body hydration produces a hypotonic (hypo-osmolar) plasma, with subsequent development of an osmotic gradient between the hypotonic plasma and the relatively hypertonic state of the normal cerebral tissue.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Fluid moves from the plasma into the brain. In this type of edema, the blood-brain barrier remains intact. If it did not, the change in plasma osmolarity would soon be transmitted to the brain tissue (through vascular leakage) and would abolish the necessary osmotic gradient. Fluid accumulation occurs primarily intracellularly, but can also be present extracellularly. In addition, typically a pronounced increase occurs in the rate of formation of CSF originating from the choroid plexus and the extracellular fluid of the brain.

The gross lesions that accompany cerebral edema are the result of enlargement of an organ in an enclosed, limited space; the degree of swelling obviously determines the type and extent of lesions that develop. In evaluating lesions, it is particularly important initially to examine the brain and spinal cord in the fresh state and in situ.

Microscopically, in contrast to some other tissues, such as the lungs, the extracellular fluid associated with vasogenic edema fluid is often not detectable, except in instances of marked vascular injury. When the extracellular space-occupying fluid cannot be identified, only its effects (separation of the cells and their processes causing reduced staining intensity) can be recognized. Additionally, following prolonged vasogenic edema, the lesions include hypertrophy and hyperplasia of astrocytes, activation of microglia, and demyelination. Cytotoxic edema is characterized by cellular swelling, including swelling of astrocytes.

Because of compression against the cranium, an affected brain has flattened gyri and shallow sulci, and it can shift in position. If the edema is confined to one side, the displacement is unilateral, which can be associated with herniation of the cingulate gyrus under the falx cerebri; the extent of the unilateral intracerebral enlargement can be best appreciated following the examination of transverse sections. Diffuse swelling usually causes a caudal shifting that can result in herniation of the brain (parahippocampal gyri of temporal lobes) beneath the tentorium cerebelli (Fig. 14-86) or herniation of the cerebellar vermis through the foramen magnum, resulting in “coning” of the vermis (Fig. 14-87). On a cut surface, the white matter is most often affected (frequently with the vasogenic type of edema, which is the most common). It is swollen and soft, has a damp appearance, and is light yellow in the fresh, unfixed state.

14.1.2.4.3

### FELINE ISCHEMIC ENCEPHALOPATHY

The cause of feline ischemic encephalopathy has not been definitively established. Although specific vascular lesions (thrombosis or vasculitis) have been found in only a few cases, an ischemic mechanism is suspected and is consistent with the character of the brain damage. Recent evidence strongly supports an aberrant cerebrospinal migration of *Cuterebra* larva following entry into the brain via the nasal cavity. A vascular-mediated vasospasm of the middle cerebral artery, resulting from hemorrhage or a toxin elaborated by the parasite, has also been proposed. Possible excitotoxic effects of a parasitic toxin have also been suggested.

925

926

Fig. 14-86 Gyrus herniation, parahippocampal gyri, brain, transverse section, caudal face, at level of the rostral colliculi and crus cerebri, horse. The caudal displacement of the parahippocampal gyri (*arrows*) was caused by a sudden swelling of the brain (increase in intracranial pressure) from severe cerebral blunt force trauma to the head. The other cerebral gyri are swollen and flattened and sulci are indistinct (cerebral edema). (*Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

**Fig. 14-87 Coning of the cerebellar vermis, brain, cat. A, Sagittal section.** Coning of the cerebellum. The caudal cerebellar vermis has been displaced caudally through the foramen magnum, note the notch on the dorsal surface (*arrow*). This result has compressed the medulla oblongata (*MO*), which can cause death from compression of the respiratory center. Note the elevation of the corpus callosum (*CC*) and focal compression of the rostral cerebellar vermis by the tectum (quadrigenal plate) (*QP*). **B, Coning of the cerebellum through the foramen magnum, caudal view through the foramen magnum.** Note that in this case not only has the cerebellar vermis (upper) been displaced caudally but also the medulla. The caudal cerebellar peduncles have been displaced caudally as far as the foramen magnum. (*A, Courtesy Dr. D. Cho, College of Veterinary Medicine, Louisiana State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. B, Courtesy College of Veterinary Medicine, University of Illinois.*)

The gross lesions are unilateral or, uncommonly, bilateral necrosis (but not symmetric) of the white and gray matter of the cerebral hemispheres, usually in the area supplied by the middle cerebral artery ([Fig. 14-88](#)). The necrosis can be multifocal or involve up to two thirds of one hemisphere. Hemorrhages can occur in the CNS or leptomeninges. In chronic cases, cerebral atrophy, most severe adjacent to the middle cerebral artery of the affected hemisphere, can occur. Microscopically, lesions include vasculitis, thrombosis, ischemia, and infarction, and the cerebral cortical lesions follow the sequence of changes in infarction listed in [Table 14-1](#).

Feline ischemic encephalopathy has a peracute to acute onset and affects cats of any age. Clinical signs usually reflect unilateral cerebral involvement. The disease most often occurs in the summer months and is accompanied by signs that can include depression, mild ataxia, seizures, behavioral changes, and blindness.

## Pathologic Basis of Veterinary Disease, 4th Edition

14.1.2.4.4

### ISCHEMIC MYELOPATHY (FIBROCARILAGINOUS EMBOLUS FORMATION)

Ischemic myelopathy (necrotizing myelopathy) has been described in the dog, cat, horse, pig, lamb, and turkey. Herniation of degenerative disk material into the vasculature, forming occlusive emboli, is commonly accepted, but the route taken by fibrocartilaginous material into the spinal (or cerebral) vessels is unproven. It has been suggested that trauma to a metaplastic nucleus pulposus causes it to fragment and that the pressure of trauma forces small fragments into damaged veins, venous plexuses, or small arterioles.

926

927

**Fig. 14-88** Feline ischemic encephalopathy, brain, transverse section at the junction between the left parietal and occipital lobes, level of thalamus, cat. Chronic feline ischemic encephalopathy with unilateral cerebral degeneration-atrophy. The dorsolateral aspect of the left cerebral hemisphere has undergone necrosis, followed by cyst formation and collapse after phagocytic removal of the necrotic debris. Cysts (*arrows*) have placed the previously existing parenchyma and the left lateral ventricle (*LV*) has expanded into the area of lost tissue (hydrocephalus ex vacuo). (*Courtesy Dr. R. Storts, College of Veterinary Medicine, Texas A&M University.*)

The gross lesion is an acute focal infarct involving cervical or lumbar spinal cord most commonly, but any portion can be affected (Fig. 14-89). Microscopically, emboli histochemically identical to the fibrocartilage of the nucleus pulposus of intervertebral disks occlude meningeal or CNS arteries, or veins, or both in affected areas (Fig. 14-90). Clinically, there is a sudden onset of spinal cord deficits, sometimes with cerebral involvement, in certain species. In dogs, larger breeds are more commonly affected. The

## Pathologic Basis of Veterinary Disease, 4th Edition

disease occurs in young and old animals. One study reported that 60% of confirmed cases of canine ischemic myelopathy had a history of trauma or exercise.

14.1.2.4.5

### NONLIPID ARTERIOSCLEROSIS

Arterial fibrosis occurs more frequently in older animals and has been described in dogs and horses. In the dog, fibrosis of the intima, media, or adventitia occurs with some frequency in cerebrospinal vessels of all types and caliber. Fibrous thickening of the adventitia of small meningeal and CNS arteries can be accompanied by variable degree of extension of fibrosis into other layers of the vessel wall. A preferential site is the choroid plexus. In old horses, a similar pattern of fibrosis occurs in vessels, and the adventitia may be preferentially affected. Amyloid deposits in meningeal and cerebral vessels are reported in older dogs and other animals. Mineralization (deposition of calcium or iron salts) of cerebral blood vessels occurs in the brains of several species, but is especially common in adult horses. Vessels of the internal capsule, globus pallidus, cerebellar dentate nucleus, and infrequently the hippocampus are preferentially affected in horses, cattle, and less commonly, dogs. Meningeal vessels in old cats, old horses, and cattle, and vessels of the choroid plexus in old cats are other sites of vascular mineralization. Overt ischemic damage is rarely associated with these nonlipomatous vascular lesions in any species; therefore clinical signs are not seen with this lesion.

**Fig. 14-89 Spinal cord infarction (ischemic necrosis), dog.** The yellow-brown region of necrosis (*arrows*) in the right lateral and ventral funiculi was the result of fibrocartilaginous emboli that occluded branches of the ventral spinal artery and obstructed blood flow. (*Courtesy Dr. J. Edwards, College of Veterinary Medicine, Texas A&M University; and Dr. J. King, College of Veterinary Medicine, Cornell University.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

14.1.2.4.6

### PERIPARTUM ASPHYXIA SYNDROME

Peripartum asphyxia syndrome (dummy foal, neonatal maladjustment syndrome, or barker foal) is attributed to impairment of normal umbilical blood flow between the mare and foal during parturition, resulting in decreased vascular flow to the brain. Causes usually are those related to interruption of umbilical blood flow, such as a twisted or pinched umbilical cord as occurs in a dystocia or premature separation of the placenta, possibly caused by endophyte fescue toxicity.

Gross lesions are laminar cortical necrosis and look similar to those described for bovine polioencephalomalacia. In the early stages of the disease, the cerebral gyri are edematous and swollen.

The cortex may have a yellow-gray discoloration distributed in a laminar pattern several days after onset of the disease. If the animal survives for a longer period of time, there is cerebrocortical atrophy.

Microscopically, initial lesions consist of laminar cortical edema and neuronal necrosis, followed by glial cell accumulation and phagocytosis of cellular debris.

927

928

**Fig. 14-90 Fibrocartilagenous embolus, spinal cord, dog.** **A**, Vascular occlusion and infarction. Fibrocartilagenous emboli have obstructed the dorso-lateral artery (*top left*) and branches of the ventral spinal artery to the right ventral gray horn and adjacent white matter, causing infarction (*arrows*). ## Pathologic Basis of Veterinary Disease, 4th Edition

---

Clinical signs in foals with peripartum asphyxia syndrome include barking like dogs, seizures, aimless wandering, absence of a suckling reflex, and loss of affinity for the mare. Affected foals are usually normal for the first 12 to 24 hours and then decline rapidly as neuronal necrosis ensues.

### 14.1.2.5 LYSOSOMAL STORAGE DISEASES

Dysfunction of lysosome-mediated degradation of products (substrates) of normal cellular metabolism results in diseases referred to as lysosomal storage diseases. These substrates cannot be degraded by lysosomes and the accumulated substrate eventually results in death of the affected cells.

Cell death is the end point of a chronic and progressive process of substrate accumulation that interferes with cellular biochemical processes and transport systems. When neurons or myelinating cells die, they release their accumulated substrate into adjacent tissue. Macrophages are recruited from the blood stream as monocytes and they phagocytose cellular debris and unprocessed substrate released from dead cells. Macrophages, however, have the same genetic defect and thus also accumulate substrate in their lysosomes. Although less vulnerable to the effects of substrate accumulation, macrophages eventually die and their released substrate is phagocytosed by additional macrophages recruited from the blood.

Lipid storage diseases, such as globoid cell leukodystrophy, are covered in more detail later. Features of some selected lysosomal storage diseases of animals are provided in [Table 14-10](#). For a comprehensive overview, the reader is referred to a review by Jolly and Walkley (1997).

Lysosomal storage diseases were originally thought to develop exclusively because of mutations that result in a reduction in lysosomal enzyme synthesis. More recently, however, it has become clear that there are other defects such as the following:

1. Synthesis of catalytically inactive proteins that resemble normal active enzymes
2. Defects in posttranslational processing (glycosylation, phosphorylation, addition of fatty acids in the Golgi) of the enzyme, which results in it being misdirected to sites (extracellular) other than to lysosomes
3. Lack of enzyme activator (an enzyme that normally increases the rate of an enzyme-catalyzed reaction) or protector protein (facilitate repair and refolding of stress-damaged proteins)
4. Lack of substrate activator protein required to assist with the hydrolysis of substrate
5. Lack of transport protein required for elimination of digested material from lysosomes

Characterization of lysosomal disorders has therefore been broadened to include involvement of any protein that is essential for normal lysosomal function.

The best-known diseases are characterized by accumulation of the substrate or substrate precursors and sometimes even by the absence of a critical metabolic product for normal lysosomal function. As a general principle, cell swelling and cytoplasmic vacuolation occur because of the accumulation of unprocessed substrate in the lysosomes; therefore differences in the size and appearance of cells (neurons versus hepatocytes) depend on the availability of the substrate (carbohydrate or lipid) in the organ system. Many

928  
929

## **Pathologic Basis of Veterinary Disease, 4th Edition**

---

lipids and glycolipids are unique to the nervous system and thus, when there is a lysosomal defect, neural cells often accumulate the substrate.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 14-10 Classification of Selected Lysosomal Storage Diseases That Involve the Central Nervous System of Animals

Disease	Storage Product	Deficient Enzyme	Species	Breed
GM <sub>1</sub> gangliosidosis	GM <sub>1</sub> ganglioside	$\beta$ -Galactosidase	Bovine	Holstein-Friesian
			Canine	Beagle, English springer spaniel, Portuguese water dog, Alaskan huskies
			Feline	Siamese, domestic shorthair
			Ovine	Suffolk, Coopworth-Romney
			Canine	German shorthair pointer, Japanese spaniel
GM <sub>2</sub> gangliosidosis	GM <sub>2</sub> ganglioside	$\beta$ -Hexosaminidase	Feline	Domestic shorthair, Korat
			Porcine	Yorkshire
			Canine	West Highland terrier
			Feline	Cairn terrier, miniature poodle, blue tick hound, beagle, Pomeranian
			Feline	Domestic shorthair, domestic longhair
Globoid-cell leukodystrophy (Krabbe's-like disease)	Galactosylceramide (galactocerebroside) and galactosylsphingosine (psychosine)	Galactosylceramidase(galactocerebroside $\beta$ -galactosidase)	Ovine	Polled Dorset
			Bovine	Angus, Murray gray, Galloway
			Feline	Persian, domestic shorthair
			Caprine	Nubian
			Bovine	Salers
$\alpha$ -Mannosidosis	Mannose-containing oligosaccharide	$\alpha$ -Mannosidase	Canine	Plott hound (type I, Hurler's disease), miniature pinscher (type VI, Maroteaux-Lamy disease)
$\beta$ -Mannosidosis	Mannose-containing oligosaccharide	$\beta$ -Mannosidase	Breed?	(type VII, Sly disease)
Mucopoly-saccharidosis	Different glycosaminoglycans	Several different enzyme deficiencies	Feline	Domestic shorthair (type I, Hurler's disease)
			Breed?	(type VI, Maroteaux-Lamy disease)
			Domestic shorthair	(type VII, Sly disease)
			Caprine	Nubian (type III, Sanfilippo's disease)

## Pathologic Basis of Veterinary Disease, 4th Edition

Ceroid-lipofuscinosis	Subunit c of mitochondria ATPase	Prelysosomal defect?	Canine	English setter, border collie, Tibetan terrier
			Ovine	South Hampshire
			Bovine	Devon

	Activating proteins A and D		Ovine	Swedish Landrace
Niemann-Pick type c disease	Unknown	Unknown	Canine	Chihuahua, cocker spaniel, Saluki, terrier-cross, blue heeler, Yugoslavian shepherd, Dalmatian, Australian cattle dog, golden retriever, dachshund, corgi
			Ovine	Rambouillet
			Bovine	Beefmaster
			Feline	Siamese, domestic shorthair
	Primarily ganglioside in neurons	Unknown	Feline	Breed?
?, Unknown; <i>ATPase</i> , adenosine triphosphatase.			<b>Canine</b>	<b>Boxer</b>

929

Examples of lysosomal storage diseases that affect human beings and animals are the gangliosidoses. With few exceptions, these diseases are inherited in an autosomal recessive pattern. They are also often gene-dose dependent, and correspondingly, recessive homozygotes manifest the disease, whereas heterozygotes are phenotypically and functionally normal, but the effected enzyme's activity is reduced by approximately 50% of normal. The age of onset of clinical signs and the severity of the disease process can vary among the different diseases because the deficiency of the involved enzyme is not always the same. If the gene defect is such that the mutant enzyme is not synthesized at all, there is an early onset of a severe disease. Conversely, if there is some residual synthesis of the deficient enzyme, later onset and a milder form of the disease result because partial catabolism of the accumulated substrate permits a longer period of time before the lysosomes are so distended with substrate that they cause loss of cell function.

930

Gross lesions of the CNS vary among the different types of lysosomal storage diseases. Brain atrophy occurs with globoid leukodystrophy in latter stages of the diseases because of the loss of myelin. Brain atrophy can also be seen with ceroid-lipofuscinosis but is not prominent in other lysosomal storage diseases, although brains of animals with gangliosidoses can have a firm, rubbery consistency. Microscopically, affected neurons often have a foamy, finely vacuolated, or granular cytoplasm, which is a reflection of the degree to which the stored material is removed during histologic processing (Fig. 14-91). The specific features of the stored material can be best appreciated by ultrastructural examination.

**Fig. 14-91 Lysosomal storage disease, brain stem, neuron cell bodies, cat.**

Note the enlargement of the neuron cell bodies, displacement of nuclei, and accumulation of unprocessed substrate in the cytoplasm of the neuronal cell bodies (*arrows*) giving the appearance of “foamy” cytoplasm. H&E stain. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

Ceroid-lipofuscinosis is a lysosomal storage disease characterized by abnormal sphingolipid (lipopigments) metabolism that occurs in cats, dogs, cattle, and sheep. Its lysosomal dysfunction has not been clearly identified, but experimental studies have shown alterations in the activity of palmitoyl-protein thioesterase and concentration of acid protease. The disease resembles other lysosomal storage diseases in that it can have a recessive mode of inheritance, but it is dissimilar in that it has no gene-dose effect. Brain atrophy occurs with ceroid-lipofuscinosis in later stages of the diseases (in sheep) (Fig. 14-20). The atrophy, which most frequently involves the cerebral cortex but also sometimes the cerebellum, can result in a 50% reduction in brain weight. The cerebral hemispheres are increased in firmness and often have a tan color, whereas the gyri are thinned and the sulci widened, a clear indication of cerebrocortical atrophy. Microscopically the cytoplasm of affected neurons has an eosinophilic granular material (with H&E staining) and a decrease in the number of neurons. Reactive astrogliosis is prominent, and microgliosis may also be observed.

### 14.1.2.6 DISEASE PROCESSES AFFECTING MYELIN FORMATION AND MAINTENANCE

#### 14.1.2.6.1 HYPOMYELINATION AND DYSMYELINATION

Disorders of myelin formation include hypomyelination and dysmyelination. Hypomyelination is a process in which there is underdevelopment of myelin. *Dysmyelination* refers to the formation of biochemically defective myelin. Hypomyelination and dysmyelination most often occur in the early postnatal period and have similar clinical and pathologic features. There are some

## Pathologic Basis of Veterinary Disease, 4th Edition

---

differences in the lesions and the mechanisms by which they develop. Some of these diseases in domestic animals are outlined in [Table 14-11](#).

14.1.2.6.1.1

### Hypomyelinogenesis

14.1.2.6.1.1.1

#### Diseases caused by viruses

Classical swine fever (hog cholera) virus, a pestivirus, can be teratogenic in the porcine fetus. The best-known neural defects resulting from fetal infection are hypomyelinogenesis and cerebellar hypoplasia, although other lesions of the CNS, such as microencephaly and nonneural tissue, have been reported. The mechanism of lesion development has not been definitively determined, but a persistent infection that results in inhibition of cell division and function of selected tissues has been proposed.

Border disease viral infection (also a pestiviral infection) is capable of inducing maldevelopment in the CNS and nonneural tissues (skeleton) of lambs and goats after natural infection of the dam during pregnancy. One of the characteristic lesions in the CNS is hypomyelinogenesis, primarily affecting the white matter of the cerebrum and cerebellum. Grossly, it may be difficult to distinguish between white and gray matter in transverse sections of cerebrum and cerebellum. The brain and spinal cords from affected lambs may be smaller when compared with unaffected lambs. The PNS is unaffected. Hypomyelinogenesis may be related to a viral-induced decrease of myelin-associated glycoprotein, myelin basic protein, and activity of nucleotide phosphodiesterase in oligodendroglia. Other lesions detected in lambs include early inflammation, porencephaly-hydranencephaly, cerebellar malformation including hypoplasia, microencephaly, and reduction in diameter of the spinal cord.

930

931

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 14-11 Hypomyelinogenesis and Dysmyelination in Animals

Species	Breed	Disease Designation	Genetic Cause	Infectious Cause	Metabolic Cause
Canine	Dalmatian	Hypomyelinogenesis			
	Chow Chow	Dysmyelination	Suspected		
	Springer spaniel	Shaking pups (hypomyelination)	Sex-linked recessive		
	Samoyed	Tremor (hypomyelination)	Suspected		
	Lurcher	Tremor syndrome (hypomyelination)			
Bovine	Weimaraner	Hypomyelination	Suspected		
	All breeds	Bovine virus diarrhea (dysmyelination)		Bovine virus diarrhea (pestivirus)	
	Charolais	Progressive ataxia	Suspected		
Porcine	Landrace	Congenital tremor (myelin agenesis)	Sex-linked recessive		
	Saddleback	Congenital tremor	Autosomal recessive		
	Chester-white	Myoclonia congenita	Autosomal recessive	Suspected	
	All breeds	Congenital tremor (dysmyelinogenesis and cerebellar hypoplasia)		Classical swine fever (pestivirus)	
	All breeds	Congenital tremor (dysmyelinogenesis)		Unknown virus	
	All breeds	Congenital ataxia and tremor (hypomyelinogenesis and cerebellar hypoplasia)		suspected	Trichlorfon (acaricide)
	All breeds	Border disease (hypomyelinogenesis/dysmyelination)		Border disease virus (pestivirus)	

14.1.2.6.1.2

### Globoid Cell Leukodystrophy

As discussed previously, *lysosomal storage* generally refers to a cellular alteration in which an increased amount of substrate material, which normally is degraded, accumulates within lysosomes, often eventually resulting in cell death. These diseases have a hereditary basis, occur in young animals, and are transmitted in an autosomal recessive pattern. Features of some selected lysosomal storage diseases of animals are given in Table 14-10.

Globoid cell leukodystrophy, a sphingolipidosis, is a lysosomal storage disease with its principal lesion being primary demyelination involving oligodendrocytes of the CNS and Schwann cells of the PNS. The disease, which has an autosomal recessive inheritance in the Cairn and West Highland white terrier, is generally seen in younger animals, often younger than 1 year old. It has also been described in beagles, miniature poodles, basset hounds, pomeranians, blue tick hounds, and in domestic shorthaired and longhaired cats.

Mechanistically the proposed sequence of events in this disease includes: (1) early "normal" myelination that progresses up to a certain stage; (2) disruption of normal myelin turnover because of deficient galactosylceramidase activity; (3) degeneration and necrosis of myelinating cells because of the accumulation of psychosine; (4) primary demyelination following degeneration of these cells; (5) recruitment of phagocytes, both resident microglia and trafficking blood monocytes; and (6) infiltration

931

932

## Pathologic Basis of Veterinary Disease, 4th Edition

---

of macrophages, which become globoid cells after phagocytosing myelin byproducts into the nervous tissue. The last-named changes occur in response to the demyelination and unmetabolized galactocerebroside.

Affected oligodendroglia and Schwann cells are deficient in the lysosomal hydrolase, galactosylceramide  $\beta$ -galactosidase (GALC), which is responsible for degradation of galactosylsphingosine (psychosine) and galactosylceramide (galactocerebroside). Psychosine is highly toxic and because it is not degraded, it has been hypothesized that it accumulates during the disease and causes direct injury to oligodendrocytes and Schwann cells, possibly through an apoptotic mechanism of cell death, in part, mediated by psychosine-induced production of cytokines and iNOS.

In globoid cell leukodystrophy, the composition of myelin is not qualitatively abnormal. Galactosylceramide is highly concentrated in myelin but is nearly absent in systemic organs except for the kidney. Peak synthesis and turnover of galactosylceramide coincides with the peak period of myelin formation and turnover during the first year of life. GALC activity also increases in relation to the galactosylceramide peak. Myelination continues at a slower rate as animals mature, and in an adult myelin formation is stable with minimal turnover.

A deficiency in GALC activity results in the accumulation of galactosylceramide, especially during the early phase of myelin maturation and turnover, and results in the formation of globoid cells discussed later. Psychosine also accumulates leading to rapid and massive degeneration of oligodendroglia and Schwann cells, extensive myelinolysis, and reduction in myelination.

Gross lesions of the CNS are characterized by a gray discoloration of the white matter, especially of the centrum semiovale of the cerebral hemispheres and white matter of the spinal cord (Fig. 14-92). The lesion in the spinal cord tends to start in the peripheral white matter and spread inward. Microscopically, such areas have pronounced loss of myelin (Fig. 14-93) and prominent “globoid” cells containing galactocerebroside that can be demonstrated with a periodic acid–Schiff stain (Fig. 14-94). Peripheral nerves are also affected and lesions are typified by primary demyelination and secondary axonal degeneration. Small sensory branches of peripheral nerves are useful sites to take biopsies to make diagnoses (Fig. 14-115).

Clinically, affected animals are ataxic and have limb weakness and tremors that progress to paralysis and muscular atrophy. Poor vision or blindness may also occur.

14.1.2.6.1.3

### Spongy Degeneration (Status Spongiosis)

Spongy degeneration is a group of diseases of young animals characterized by a spongy lesion (referred to here as status spongiosus) that primarily occurs in the white matter of the CNS but also extends into the gray matter. Status spongiosus is a somewhat nonspecific term and can develop by several different mechanisms. It includes a variety of lesions, such as splitting of lamella forming myelin sheaths (characteristic of the diseases discussed here), accumulation of extracellular fluid (extracellular cerebral edema), swelling of cellular processes (astrocytic, neuronal), and Wallerian degeneration at a later stage when the necrotic myelin and axons have been phagocytosed and the spaces once occupied by these structures are empty.

932

933

**Fig. 14-92 Globoid cell leukodystrophy, brain, transverse section at the level of the mammillary body, dog.** The white matter, especially of the gyri, has an off-white appearance (*arrows*). Macrophages (globoid cells) derived from blood monocytes (also enzymatically deficient in  $\beta$ -galactocerebrosidase) accumulate in white matter to phagocytose galactocerebroside and oligodendroglial debris secondary to the toxic effects of galactosylsphingosine (psychosine) on oligodendroglia (and in the peripheral nervous system Schwann cells). There is also bilateral hydrocephalus of the lateral ventricles, presumably hydrocephalus ex vacuo, as a result of the loss of neurons and their axons. (*Courtesy Dr. H.B. Gelberg, College of Veterinary Medicine, Oregon State University.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Gross brain lesions reported for spongy degeneration range from no gross lesions to swelling, edema, and pallor of the white matter, and dilation of the ventricles. Microscopically the lesion is characterized by variably sized empty spaces within the white matter. Ultrastructurally, with spongy degeneration and some other disease processes characterized by status spongiosus, there is splitting or separation of the myelin sheath at the intraperiod line with the formation of large intramyelinic spaces. In some cases myelin formation is deficient.

Some species and breeds affected with spongy degeneration include the canine (Labrador retriever, Saluki, silky terrier, Samoyed), feline (Egyptian mau), and bovine (Jersey, shorthorn, Angus shorthorn, Hereford), and an autosomal recessive mode of transmission has been proposed for some forms of this disorder. A unique form of the spongy degeneration also occurs in a group of metabolic inherited diseases called aminoacidopathies.

Not to be confused with spongy degeneration is the term *spongiform change*. Spongiform change is characterized by small clear vacuoles of varied sizes that form in the cytoplasm of neuron cell bodies and proximal dendrites in diseases such as the TSEs and rabies encephalitis and in the processes of astrocytes that are spatially related to the affected neurons.

14.1.2.6.2

### DEMYELINATION

Demyelination, which means degeneration and loss of myelin already formed, can be divided into primary and secondary types. *Primary demyelination* refers to a disease process in which the myelin sheath is selectively affected, with the axon remaining essentially intact. *Secondary demyelination*, a designation criticized by some, refers to “secondary” degeneration of myelin following “primary” injury to and loss of the axon, as in Wallerian degeneration, and is not a selective injury of the myelin sheath.

Injury to oligodendroglia that results in myelin sheath breakdown or direct injury to myelin sheaths cause the release of lipids and other myelin components into the extracellular space. These materials readily activate microglial cells and attract blood monocytes, which phagocytose myelin debris.

14.1.2.6.2.1

### Metabolic Causes

14.1.2.6.2.1.1

### Osmotic demyelination syndrome

In human beings this syndrome is termed central or extrapontine myelinolysis. The disorder was first reported in 1959, and the majority of cases were in severely malnourished alcoholics. Since then, the disorder has been observed in a variety of clinical disease states. A major risk factor is chronic hyponatremia treated in hospitals by the administration of intravenous saline solution. The disease has been experimentally reproduced in dogs and laboratory rodents by inducing hyponatremia, allowing a period of stabilization (3 to 4 days is sufficient), and then administering saline-containing fluids.

Two cases of osmotic demyelination syndrome have been reported in the veterinary literature, and one of the authors has observed a case. In all three, there has been a clinical diagnosis of Addison's disease. Treatment consisted of intravenous administration of fluids containing normal saline solution to correct the hyponatremia typical of hypoadrenocorticism. The reported rates of correction have been 22 mmol/L in 24 hours and 16.4 mmol/L in 24 hours. In the author's case, serum sodium

## Pathologic Basis of Veterinary Disease, 4th Edition

increased by 42 mmol/L in 4 days. All these rates of correction exceed the limits established for human beings and are consistent with human cases of the syndrome.

The pathogenesis of osmotic demyelination syndrome is thought to be opposite to that occurring with salt poisoning (i.e., a hyponatremic to hypernatremic shift following saline administration). 933

Lesions occur in areas of the brain where there is a confluence or intermingling of gray and white matter. Rapid (within 24 to 48 hours) correction of chronic hyponatremia from an established equilibrium exceeds the adaptive responses of the brain, resulting in myelin destruction. The exact mechanism of demyelination is not known. It is proposed that osmotic imbalance and water shifts induce osmotic stress in the CNS that result in myelin destruction. 934

In contrast to human beings, gross lesions in dogs are either not apparent or subtle. Slight softening and discoloration has been observed in affected brain regions. Microscopically, lesions can be limited to the reticular formation at the level of the pons or can be extensive, affecting cerebellar folia, midbrain, thalamus, basal nuclei, and at the interface of the corona radiata and cerebrocortical gray matter. In affected areas, the white matter is pale in routine H&E stained sections and is heavily infiltrated with foamy macrophages. Special stains (Luxol fast blue for myelin), confirm acute myelin destruction and accumulation of myelin debris in macrophages. As is typical of strictly demyelinating lesions, axons are well preserved.

14.1.2.6.2.2

### Circulatory and Physical Disturbances

Physical compression of CNS tissue that results from various causes usually chronic in nature can also induce demyelination. Some possible mechanisms include compression of myelin sheaths and oligodendroglia, interference with circulation resulting in CNS ischemia, and disease processes resulting in the accumulation of extracellular fluid.

It is well known that vasogenic and hydrostatic edema caused by inflammation, neoplasms, trauma, and obstructive hydrocephalus can cause degeneration of myelin sheaths. The underlying mechanisms for this injury are multiple and include creation of a hypoxic-anoxic environment, degeneration of oligodendroglia, and alteration in stability of the myelin sheath, permitting entrance of injurious proteolytic enzymes from the surrounding environment.

14.1.2.6.2.3

### Diseases Caused by Microbes

14.1.2.6.2.3.1

#### Viruses

14.1.2.6.2.3.1.1

#### Canine distemper.

Canine distemper is one of the most important diseases of the canine species. It is caused by a morbillivirus (family Paramyxoviridae) and has a worldwide distribution. Morbilliviruses other than CDV include measles virus, rinderpest virus, peste des petits ruminants virus, phocine distemper virus of seals, equine morbillivirus, and dolphin and porpoise morbilliviruses. The virus is pantropic and has a particular affinity for lymphoid and epithelial tissues (lung, gastrointestinal tract, urinary tract, skin) and the CNS (including the optic nerve) and eye. In the CNS, there is demyelination without any substantial amount of inflammation.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Dr. Brian Summers (Cornell University, College of Veterinary Medicine) has commented on the sequence of events in CDV infection based on his studies of its pathogenesis. CDV is spread between dogs by aerosol transmission. The virus is trapped in the mucosa of the nasal turbinates (centrifugal turbulence), infects local macrophages, and is spread by macrophages (leukocytic trafficking) to regional lymph nodes (retropharyngeal). CDV replicates in these regional lymph nodes and replication is followed by a primary viremia that infects systemic lymph nodes, spleen, and the thymus approximately 48 hours after exposure. With infection of the lymphoid system, immunosuppression can occur resulting in secondary bacterial infections, such as conjunctivitis, rhinitis, and bronchopneumonia, which are commonly seen in CDV infections.

Four to 6 days after the primary viremia, a secondary viremia occurs largely via leukocytic trafficking. CDV spreads from cells of the lymphoid system to infect the CNS and epithelial cells of the respiratory mucosa, urinary bladder mucosa, and gastrointestinal tract. In the CNS, trafficking leukocytes form perivascular cuffs, and from these cells CDV is disseminated throughout the CNS. It should be noted that the degree of inflammation in the CNS at this stage is minimal.

Under laboratory conditions, the severity of the disease and the cell populations and areas infected in the CNS depend on the (1) age of the dog, (2) strain of CDV, and (3) kinetics of the antiviral immune response. Virtually all cells of the CNS including the meninges, choroid plexus, neurons, and glia are susceptible to infection, but oligodendrocytes are novel in that the infection in these cells is usually defective (incomplete). In dogs infected experimentally with the A75-17 strain of CDV, isolated from a dog with CDV in 1975, approximately a third of the dogs died from encephalomyelitis and the effects attributable to severe immunosuppression. A third of infected dogs developed a timely systemic immune response, and the CNS disease was quickly resolved and they recovered. Finally, a third of the dogs infected with CDV developed a subacute to chronic inflammatory/demyelinating disease of the white matter with some gray matter involvement because of a delayed and deficient immune response.

The encephalomyelitis of canine distemper is initiated following viral entry into the CNS, perhaps 1 week after exposure to CDV. Leukocytic trafficking spreads CDV to the gray and white matter of the CNS and to epithelial cells and macrophages of the choroid plexuses. The virus is shed from choroid plexus epithelial and ependymal cells into the CSF in infected macrophages. It is disseminated throughout the ventricular system, infects ependymal cells lining the ventricular system, and then spreads locally to infect astrocytes and microglia. Periventricular white matter lesions, especially those surrounding the fourth ventricle, are the result of this sequence of events.

934  
935

By 25 days after exposure, CDV-infected leukocytes in the perivascular cuffs have disappeared; however, lesions in the white matter consist of periventricular foci of myelin degeneration and swollen astrocytes. CDV infects astrocytes, microglia, and other cells. Microglia and recruited blood monocytes phagocytose myelin fragments.

Inflammatory mediators released from lymphocytes, microglial cells, and trafficking macrophages result in expansion of the initial lesions. These inflammatory mediators may cause necrosis of cells and cell processes in the focus but do not result in a “selective” demyelinating process affecting axons. The characteristic white matter vacuolation (intramyelinic edema) seen in H&E stained sections of CDV-infected CNS is apparently caused by a direct effect of the virus

## Pathologic Basis of Veterinary Disease, 4th Edition

on oligodendrocytes, as it appears in the earliest white matter lesions before they have acquired an “inflammatory” character—a dense infiltrate of lymphocytes, monocytes, and plasma cells.

Gross lesions characteristically occur in the cerebellum (medullary area, folial white matter, and subpial white matter) and cerebellar peduncles (with both white matter and sometimes gray matter involvement of the pons). Lesions also occur in medulla oblongata (particularly in the subependymal area of the fourth ventricle), rostral medullary vellum, cerebrum (both white matter and gray matter), optic nerves, optic tracts, spinal cord, and meninges.

Microscopically, in addition to demyelination there is status spongiosus, astrocytic hypertrophy and hyperplasia with focal and variable syncytial cell formation, reduced numbers of oligodendroglia, and variable neuronal degeneration. Inclusion bodies (cytoplasmic, nuclear, or both) are detectable, particularly in astrocytes, which are important target cells for the distemper virus, but also in ependymal cells and occasionally in neurons (Fig. 14-95). The earliest evidence of myelin injury is a ballooning change resulting from a split in the myelin sheath, or more degenerative changes including axonal swelling. This lesion is also variably associated with astroglial and microglial proliferation. This initial injury of the myelin sheath, which has been suggested to be a result of perturbed astrocytic function following viral infection, is followed by a progressive removal of compact myelin sheaths by phagocytic microglial cells that infiltrate the myelin lamellae and variable axonal necrosis.

**Fig. 14-95 Canine distemper inclusion bodies, brain, midbrain periventricular white matter, dog.** Distinct acidophilic (red) intranuclear inclusion bodies (arrows) are present in astrocytes and some gemistocytes. Similar inclusions can be observed in the cytoplasm of epithelial cells throughout the body (bladder epithelium, respiratory epithelium, gastric epithelium). H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

A late stage of demyelination, which is a reflection of an affected animal's improved immune status, is more pronounced and is characterized by nonsuppurative inflammation (perivascular cuffing, leptomeningitis, and choroiditis) and also can be accompanied by tissue degeneration and accumulation of gitter cells.

In addition to the dog, animals of the families Ailuridae (red panda), Canidae (fox, wolf), Hyaenidae (hyena), Mustelidae (ferret, mink), Procyonidae (raccoon, panda), Ursidae (bear), Viverridae (civet, mongoose), and Felidae (exotic felids including lions, tigers, and leopards) are also reported to be susceptible to canine distemper viral infection. Additionally, canine distemper has recently been reported in javelinas (collared peccaries) of the family Tayassuidae in the United States.

Neurologic signs in all affected species include convulsions, myoclonus, tremor, disturbances in voluntary movement, circling, hyperesthesia, paralysis, and blindness.

14.1.2.6.2.3.1.2

### Old-dog encephalitis.

Old-dog encephalitis is thought to arise from long-term persistent infection of the CNS with a defective form of CDV. This pathogenesis has been demonstrated in experimental infections with the CDV. Although the virus has the same general polypeptide composition and contains all of the major viral proteins as the one causing conventional distemper, some differences among peptides have been reported. The mechanisms involved in development of lesions are not known; however, they result in a proliferation of nonsuppurative inflammatory cells.

935

Lesions are primarily in the cerebral hemispheres and brain stem. Microscopic lesions are characterized primarily by demyelination with a disseminated, nonsuppurative encephalitis with variable, sometimes prominent, lymphoplasmacytic perivascular cuffing, microgliosis, astrogliosis, and variable leptomeningitis and neuronal degeneration. Nuclear and cytoplasmic inclusions, positive for distemper viral antigen, have been detected in neurons and astrocytes in the cerebral cortex, thalamus, and brain stem, but in contrast to distemper, not in the cerebellum.

936

Old-dog encephalitis is a rare condition occurring in mature adult dogs. Clinical signs include depression, circling, head pressing, visual deficits, seizures, and muscle fasciculations.

14.1.2.6.2.3.1.3

### Visna.

Visna, which means wasting, is a slowly progressive, transmissible disease of sheep. The disease is caused by a strain of the ovine maedi-visna virus (MVV) complex, one of the eight basic lenti (slow) viruses (family Retroviridae). A different strain of the same virus causes a lymphocytic interstitial pneumonia referred to as maedi.

In recent years, the understanding of the factors associated with infection, including the mechanism of lesion development, has improved. Visna is a persistent viral disease that probably results from the ability of the virus to form provirus and integrate into the host genome. The virus can also change its antigenic characteristics (antigenic drift), which enables it to escape the effects of the host's immune response. Although the visna virus and other lentiviruses can infect promonocytes and monocytes in the bone marrow and blood, viral replication is restricted in these cells, where it remains as provirus DNA until maturation and differentiation to macrophages.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Primary viral replication occurs in cells of monocyte-macrophage-microglial lineage. Thus visna virus enters the CNS by way of leukocytic trafficking of virus-infected macrophages. Visna virus can also be present in oligodendrocytes and astrocytes located in foci of demyelination. It has been suggested that the virus gains access to these cells via close contact with infected monocytes. Recent studies suggest the virus can also infect and productively replicate in endothelial cells. This mechanism may provide an additional route for viral entry into the CNS and the potential for alterations of the blood-brain barrier.

Although gross lesions are not frequently observed, they may occur in areas of prominent inflammation where they appear as yellow-tan areas. Early microscopic lesions primarily affect the gray and white matter subjacent to the ependyma of the ventricular system of the brain and central canal of the spinal cord. These lesions are characterized by a nonsuppurative encephalomyelitis accompanied by pleocytosis, variable edema, CNS necrosis, astrocytosis, choroiditis, and nonsuppurative leptomeningitis. The inflammatory response is thought to be caused by the upregulation of expression of major histocompatibility complex class II genes that occurs in virus-infected macrophages. Degeneration of myelin sheaths also occurs at this time but is often accompanied by axonal degeneration, suggesting that it could be a secondary lesion, such as in Wallerian degeneration. Oligodendroglial and neuron injury and necrotic cell death are attributable to cytokines and other toxic factors secreted by inflammatory cells and glial cells. Recent *in vitro* studies suggest that caspase activation leading to apoptotic cell death may play a role in visna.

Neuronal cell bodies and oligodendroglia are normal (except in areas of necrosis) during this stage of the disease. The latter cells can become infected, however, which leads to later development of demyelination. Primary demyelination, particularly in the spinal cord, has been described in animals infected for prolonged periods (months to years). Such animals also have periventricular inflammation.

The primary demyelination that occurs during the late stages of the disease process (6 months to 8 years after infection) has been proposed to result from oligodendroglial cell infection. The main sources of excreted virus are the udder and lungs (as mainly cell-associated virus), and transmission occurs most readily between the dam and lamb via the milk and between confined individuals, probably via respiratory secretions. The MVV has also been detected in semen of infected rams. It is important to emphasize that no profound immune deficiency occurs with MVV infections, as is the case for immunodeficiency lentiviral infections that infect CD4<sup>+</sup> T lymphocytes. Nonetheless, secondary infections can still significantly accompany MVV infection.

In addition to pneumonia, MVVs can also cause mastitis, arthritis (uncommonly of the carpus or hind limb joints), and a mesangial glomerulitis. Irrespective of the target organ, the lesions are to be regarded as chronic and lymphoproliferative, in contrast to the well-known immunodeficiency infections caused by HIV-1, simian immunodeficiency virus (SIV), and feline immunodeficiency virus (FIV).

Viral strain differences and breed of sheep can influence the lesions that develop. For example, the visna form of the disease does not commonly occur in ovine breeds of North America, although some degree of visnalike lesions can be seen with maedi. Visna originally was described in Iceland, but sheep with similar lesions of the CNS have been detected in The Netherlands, Kenya, the United States, and Canada. CNS signs include an abnormal hindlimb gait that progresses to incoordination and rear limb paresis over a period of weeks or months.

936

Caprine leukoencephalomyelitis-arthritis was first described in the United States and has since been recognized in other parts of the world. The infection can be readily transmitted by colostrum and milk following birth, or by direct contact. A close relationship exists between the MVVs of sheep and the caprine arthritis encephalitis (CAE) virus, but genomic differences between them can be demonstrated. As with MVV infection of sheep, CAE viral infection is also a lymphoproliferative disease with a tropism for the macrophage, which acts as a carrier for the virus.

Gross lesions in the nervous system include tan- to salmon-colored foci of necrosis and inflammation that can occasionally be detected in the brain (Fig. 14-96) and most prominently in the spinal cord. Microscopic lesions of the nervous system are similar to those of visna (nonsuppurative encephalomyelitis) but can be more severe with CAE. Nonneural lesions include interstitial pneumonia of moderate severity in some affected kids. Such lungs fail to collapse completely and are mottled red or blue. As discussed under visna, the mechanism of infection and cell death appear similar.

The pattern of disease in CAE is age dependent. Neurologic manifestations are usually seen in young kids 2 to 4 months of age, but unlike visna in sheep, there is a more rapid progression and signs progressing to quadriplegia develop within weeks to months. As with visna, affected goats have pleocytosis. In adult goats the primary target tissue is the synovium of the joints, and animals that survive the initial infection have lymphoproliferative synovitis and arthritis develop. Pneumonia, lymphocytic mastitis, and encephalomyelitis also occur in adult animals.

**Fig. 14-96 Leukoencephalitis, caprine retrovirus-induced encephalitis, brain stem, goat.** A focal area of the brain stem (arrows) is yellow-brown and was found, microscopically, to be infiltrated by lymphocytes, plasma cells, and histiocytes. A similar lesion commonly occurs in the spinal cord. (Courtesy Dr. H.E. Whiteley, College of Veterinary Medicine, University of Illinois.)

### Progressive multifocal leukoencephalopathy

See [Appendix 14-1](#).

14.1.2.6.2.4

### Immune-Mediated Diseases

In veterinary medicine, naturally occurring immune-mediated demyelination in domestic animals is rare, and other than for canine polyradiculoneuritis (coonhound paralysis), it is usually only suspected rather than proven. These diseases are best known to occur in human beings as sequelae to postinfectious and postvaccinal events. They result in primary demyelination of the CNS. Autoimmune diseases of the CNS are mechanistically either a type II hypersensitivity (antibody-mediated) or a type IV (cell-mediated) hypersensitivity, and T lymphocytes and macrophage-derived cytokines play contributory roles.

Autoimmune injury to oligodendroglia in the CNS arising from aberrant cellular and/or humoral immune responses can result from one of the following four proposed mechanisms:

1. Molecular mimicry: The CNS has antigens that are similar or identical to those expressed by certain pathogens (virus or bacterium). The normal inflammatory and immunologic responses to these pathogens result in the expression of antibodies that cross-react with “antigens” normally expressed by CNS cells.
2. Abrogation of immune tolerance: The CNS is an “immune privileged” organ (like the eye). The immune system therefore does not recognize CNS antigens as innate antigens, and if they are exposed to the immune system following inflammation or trauma, an autoimmune response can ensue. Injury, physical or otherwise, to blood vessels within the CNS can cause the release of “sequestered antigens” into the blood stream leading to an autoimmune response.
3. Genetic factors: Functions of the immune system that are strictly regulated genetically may be under the control of abnormal inherited genes or altered normal genes that regulate immune responses to CNS antigens and thus increase the susceptibility to autoimmune diseases.
4. Stress factors: Environmental stresses mediated through the CNS can depress the functions of the immune system, leading to the formation of autoantibodies.

The mechanism of myelin breakdown in immune-mediated demyelination is not clearly understood. The initial step is thought to be exposure of antigens in myelin basic protein of the major dense line of myelin lamellae following injury. Myelin proteins are substrates for calpain, a calcium-activated neutral proteinase. Calpain has been implicated in several autoimmune diseases and may play an important role in CNS demyelination. Exposed antigens are then recognized by the immune system, and experimental studies suggest that lesions result from a complex interaction between inflammatory cells and their mediators and lamellae of myelinating cells. T lymphocytes, some B lymphocytes, and activated macrophages (recruited monocytes) and microglia cells, adhesion molecules, cytokines, chemokines, and their receptors have been demonstrated in the lesions. This interaction results in primary demyelination.

Gross lesions are usually not present but can include a gray to yellow discoloration of white matter. Microscopically, lesions are best observed in white matter and are characterized by vacuolation of

937

938

## Pathologic Basis of Veterinary Disease, 4th Edition

---

myelin and the presence of lymphocytes, macrophages, and plasma cells. Myelin sheaths degenerate from injury caused by: (1) inflammatory mediators and (2) direct actions of macrophages on lamellae. Myelin lamellae separate as a result of intramyelinic edema, fragment, and are phagocytosed by macrophages.

The best-known model of immune-mediated demyelination is an experimental model referred to as experimental allergic encephalomyelitis (EAE). EAE is produced by inducing a hypersensitivity to myelin or, more specifically, to myelin basic protein. If appropriate laboratory animals are inoculated with white matter or myelin basic protein (suspended in complete Freund's adjuvant), they become paralyzed after 2 to 3 weeks. Lesions are characterized by perivascular (perivenular) demyelination accompanied by accumulation of lymphocytes and macrophages.

A similar process, referred to as postvaccinal encephalomyelitis, occurred occasionally in human beings when human rabies vaccine contained CNS tissue. The incidence decreased after 1957 when duck embryo rabies vaccine came into use. In some cases with mild clinical signs, recovery was complete and axons were remyelinated following immune-mediated demyelination.

A third situation in which this type of demyelination occurs follows infection with certain viruses in human beings (rubeola virus) and animals (e.g., influenza virus). These diseases, which are rare and designated as postinfectious encephalomyelitis, are also characterized by development of lesions in the CNS comparable to those of EAE.

### 14.1.2.7 TRAUMATIC INJURY

Traumatic injury of the CNS is caused by physical insults such as compression, stretching, and/or laceration of neurons/axons. When the brain and spinal cord collide with the bony ridges lining the cranial vault and the bony wall of the vertebral canal, respectively, or when axial, rotational, and angular forces (Fig. 14-97) are applied to neurons and axons during trauma, the force of impact and sudden acceleration of neurons and axons, both within the CNS and in the adjacent cranial and spinal nerves, can cause them to compress, twist, stretch, and tear. Concurrently the same type of forces can injure blood vessels in the CNS and leptomeninges and may result in small hemorrhages or hematomas within the parenchyma of the brain and in the leptomeninges (subarachnoid space) (Fig. 14-98).

Diffuse brain injury (often present in concussion) is caused by acceleration/deceleration forces applied to many areas of the CNS rather than in one specific location. Diffuse brain injury involves neuronal processes, cell bodies, transmitter mechanisms, and macroglial cells and blood vessels. The most severe injury to axons appears to be at the gray matter–white matter junction. A variant of diffuse brain injury is diffuse axonal injury in which axons of large myelinated nerve fibers are injured by shearing forces. In diffuse brain and axonal injury, mechanical deformation results in physical disruption of cell membranes and cytoskeleton and increased membrane permeability, resulting in major ionic fluxes in and out of the cell. Such changes can lead to excessive release of glutamate, excitotoxicity and cell death, free radical formation, apoptosis, and delayed inflammatory responses. The end result can be Wallerian degeneration.

In general, trauma of the CNS in animals occurs less frequently than in human beings. Animals are not exposed as frequently to potentially trauma-causing situations (e.g., automobile travel) as are human beings, and there are anatomic differences (see later), including a quadruped posture, which increases stability and helps protect the brains of animals.

## Pathologic Basis of Veterinary Disease, 4th Edition

Among animals, trauma to the brain is probably most frequently caused in dogs as a result of automobile-induced injury and in cats from falls from significant heights (high-rise apartment buildings, balconies, and roofs). Even after falling from considerable heights, cats often have remarkably minor injury to the CNS. Other examples include fracture of the spinal column or cranium of jumping horses and fractious animals, such as horses and ruminants, during excitement and restraint.

Predisposition to cerebral trauma is also influenced by anatomic differences. The percentage of brain mass in relation to skull size is much less in domestic animals than in primates, and in the bovine and porcine species the cranial cavity is additionally protected dorsally by prominent frontal sinuses. Birth trauma, which can be important in human beings, is essentially insignificant in animals because in the latter the shoulders, and particularly the pelvis, rather than the head are likely to be compressed in the birth canal. Exceptions to this generalization include brachycephalic breeds of dogs. Several factors also influence the susceptibility of the spinal cord to trauma. The amount of space between the spinal cord and the wall of the vertebral canal is very important in determining the degree of injury following edema or compression with disk herniation. This space is greater in the cervical area of the dog than at the thoracolumbar level. Thus disk herniation at the latter area is more likely to result in severe spinal cord injury.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Functional factors also play an important role in brain injury. The brain of a freely movable head is much more susceptible to injury than one that is fixed in place. The increased susceptibility of the former has been attributed to the ability of the cranium (the bone) and its contents (the brain) to impact upon each other following nonpenetrating trauma. This interaction occurs because the brain does not completely fill the cranial cavity, thus resulting in a very short distance (or space) between brain and bone.

The type and location of the lesion (contusion and/or hemorrhage) will depend on the location of the point of contact and the direction of the blow, relative to the head. If the blow is directly on the back or front of the head, the head and brain will move straightforward or backward, respectively (Fig 14-97, axial). If the blow is horizontal to the top of the head or horizontal to the rostral portion, the head will rotate on the atlanto-occipital axis (angularly and rotationally, respectively). In the case of an axial blow to the back of the head (an animal falling onto the back of its head), the head and thus the cranial vault will accelerate faster than the brain, which will lag behind, and the caudal aspect of the vault may move forward and contact the caudal aspect of the cerebral hemispheres, usually the occipital cortex. In the case of an animal falling onto the back of its head, the head will accelerate abruptly and the momentum will carry the brain caudally, where it may strike the inside of the caudal brain in the cranial vault. A vertical blow delivered directly down onto the dorsal surface of the head will have the same type of result on the dorsal aspect of the cerebral hemispheres as the blow to the back of the head. It is more common, from the same blows described previously, to see hemorrhage, usually subarachnoid, on the opposite side of the point of impact with the brain. For example, a vertical blow to the top of the head causes hemorrhage of the ventral surface of the medulla and cerebral hemispheres. Thus, following an impact upon a stationary freely movable head, the bone of the cranial vault will move upon the stationary brain and injure it (coup injury), and on the opposite side the nerves and blood vessels will be stretched, possibly resulting in nerve damage and hemorrhage (contrecoup injury). In addition, the mass and velocity of the object striking the head are important. Trauma following impact of a relatively large blunt object can create notable head movement and a large-impact injury, whereas a small object such as a bullet moving at a high rate of speed can cause less head movement and a smaller but deeper area of direct tissue damage. In summary, the basic concept is the transfer of kinetic energy by the striking object to the head. A large blunt object will cause the head to accelerate without deforming it; a smaller object, such as a bullet, will penetrate.

939

940

Fig. 14-98 Leptomeningeal (subarachnoid) hemorrhage, brain, right cerebral hemisphere, dog. (Courtesy Dr. R. Storts, College of Veterinary Medicine, Texas A&M University.)

Factors involved in the protection of the brain include the rigidity of the cranium (dependent on age), the round shape of the dorsum of the skull, the structure of the parietal, occipital, and temporal cranial bones (two layers of compact bone separated by spongy bone referred to as diploë), cranial sutures, sinuses, ridges in the floor of the cranial cavity, meninges, and CSF. The spinal cord is enclosed and protected by the vertebral column, which is surrounded by soft adipose tissue and muscle. Other structures that help protect the spinal cord by absorbing shock are the intervertebral disks and the cancellous bone of the vertebrae. Vertebral ligaments maintain the alignment of the vertebral column; denticulate ligaments support the spinal cord in the middle of the vertebral canal and the meninges, and particularly the CSF cushions trauma.

Clinically, animals with CNS trauma have signs referable to the area injured, brain, or spinal cord. With brain trauma, signs can vary widely and range from unconsciousness lasting a few seconds followed by complete recovery and return to normal function to depression, abnormal behaviors, such as disorientation and irritability, semiconsciousness with responsiveness only to noxious stimuli, and unconsciousness with no response to any stimulus. With spinal cord trauma, signs vary depending on the severity of the injury and the

## Pathologic Basis of Veterinary Disease, 4th Edition

---

rate of onset. Paralysis results from severance of the cord or ruptured disks. Paresis and ataxia result from less severe injury.

14.1.2.7.1

### CONCUSSION

Concussion is often thought of as a clinical designation of temporary loss of consciousness with recovery following head injury. As in the human being, a movable head is much more susceptible to trauma than a fixed, supported one. Application of an appropriate concussive trauma to the mobile head of an animal results in a reversible cerebral dysfunction that lasts for a matter of seconds or, at most, a few minutes and is usually reversible, with stronger blows causing more severe injury and even death.

Concussive injuries of the diffuse type also occur in animals, but there are some differences between animals and human beings. For example, it is difficult to produce severe concussion in animals because the margin between the force of a stunning blow and one causing fatal injury is very small. The smaller the brain, the less vulnerable it is to rotational forces and the larger are the forces necessary to cause concussion. It should be noted, however, that concussion, particularly when there is rapid recovery from unconsciousness, can occur more frequently than appreciated in animals because the clinical signs may not be recognized.

Diffuse brain injury does not usually cause gross lesions. Microscopic lesions detected in animals include diffuse axonal injury characterized by axonal degeneration, and this may be followed by Wallerian degeneration. Damage to neurons ranges from central chromatolysis to death and neuronal loss. The more severe forms of diffuse brain injury can also have generalized acute brain swelling caused by unregulated vasodilation, which can be followed after some time by cerebral edema.

940

Spinal concussion is the term applied to the immediate and temporary loss of function that sometimes follows severe direct blows to the spinal column. Loss of function usually affects the long tracts/bundles of nerve fibers (funiculi), but usually there is no demonstrable external change in the vertebrae or spinal cord. As with cerebral concussion, there is often only a temporary functional disability of the cord after injury, but if the trauma is more severe, permanent neurologic deficits can result.

941

14.1.2.7.2

### CONTUSION

*Contusion* means bruising, which is generally associated with rupture of blood vessels, and in the cerebrum this injury results in grossly detectable lesions such as hemorrhage and can, like concussion, result in unconsciousness and even death. The factors that cause concussion and contusion can occur together in the same animal. Lesions can be superficial (cerebral gyri) or more central (brain stem), and there can be concurrent skull fractures.

Although hemorrhage is the most common lesion, contusion of the brain can also result in tearing of CNS tissue. Tearing results in tissue necrosis and neuronal loss. Two designations are used to identify the location of contusive injury. A coup contusion is located at the impact site, and a contrecoup contusion at a location on the opposite side of the brain. When the two lesions occur together (coup-contrecoup or contrecoup-coup), the first term indicates the site of most severe injury (see [Box 14-7](#) for a summary of the pathogenesis of coup-contrecoup contusion).

14.1.2.7.2.1

### Box 14-7 Pathogenesis of Coup-Contrecoup Contusion

14.1.2.7.2.1.1

#### Conditions Involved in Coup-Contrecoup Contusion

1. Head freely movable.
2. Head accelerated rapidly (by being struck by a broad object, such as an automobile) or decelerated rapidly (head strikes pavement after a fall from a standing position).
3. Because the brain does not fill the cranial vault, it may lag behind the movement of the cranium when the head is accelerated or decelerated rapidly.
4. As a result, the inside of the cranial vault may strike the stationary brain at the point of impact (coup injury), or the lesion may occur on the opposite side (contrecoup), either from the stretching and tearing of vessels at that site or by the brain being struck by the inside of the cranial vault on the opposite side when there is reduced amount of cerebrospinal fluid buffer present.

Many investigations have been made to determine the mechanisms involved in the development of contusive lesions, and the kinetics are complicated and still not completely resolved. Factors that have been considered to be significant include the ability of the head to move freely, the occurrence of a rotational movement of the brain over rough surfaces on the inside of the cranial vault, and the development within the cranial cavity of positive and negative pressures and gravitational forces. The basic results of the different types of blows to the heads of animals have been discussed previously, and it is interesting to compare these with the lesions in humans. Several neuropathologic principles have been generally accepted regarding craniocerebral contusive trauma in human beings:

1. A blow to the stationary (but freely movable) head produces a cerebrocortical coup contusion beneath the point of cranial impact, but with rare exceptions causes no cerebrocortical contrecoup contusion opposite the point of cranial impact. This outcome is not always true of animals, in which a blow to the dorsum of the head from a flat object, such as a spade, causes marked subarachnoid hemorrhage on the ventral surface (contrecoup).
2. An impact of a moving head (moving before impact, as in a fall from a standing position) against a firm or unyielding surface causes a cerebrocortical contrecoup contusion opposite the point of cranial collision (often at the poles and inferior surfaces of the frontal and temporal lobes), but with rare exceptions there is no contusion beneath the point of impact. In contrast, horses that fall backward and land on their backs and strike the occiput often have subarachnoid hemorrhage over the occipital poles of the cerebral hemispheres.
3. Falls from great heights, and crushing of the head between a strong external force and unyielding surface, are generally not associated with the occurrence of contrecoup lesions.

Dawson and co-workers proposed a mechanism for both contrecoup and coup injury of the human brain that also addressed the specific deficiencies of mechanisms that have been advanced by others. An example explaining the mechanism of contrecoup injury states that when a person falls backward from a standing position because of loss of balance, the gravitational torque acting on the body causes downward acceleration of the head in excess of the acceleration as a result of gravity. Under these circumstances the

## Pathologic Basis of Veterinary Disease, 4th Edition

brain lags toward the trailing anterior surface of the cranium before impact (causing displacement of the protective CSF layer between the brain and skull) and permits compressive stress to develop at this site, although impact occurs at the opposite side of the head. Because dissipation of the CSF at the anterior (contrecoup) site allows compressive stress to be focal at this contrecoup site and because of the shearing stress that is generated, injury occurs. In addition, a relative rotational gliding motion between the brain and skull is produced when the impact suddenly stops the skull's motion and rotation, thus creating an additive shearing stress because the fluid lubrication necessary to facilitate gliding of the brain over the cranial surface is reduced. The concentration of this rotational shearing stress is likely to occur beneath the frontal and temporal lobes because of the rough surface of the skull that exists in this location. In contrast to contrecoup injury, coup contusions occur infrequently in this type of fall. In such situations, the brain lags away from the impact site, which results in a thickening of the protective CSF layer between the brain and skull immediately beneath the point of impact, which helps explain the absence of coup injury in primates and human beings in typical moving head trauma. 941 942

Coup injury in human beings can occur when a stationary but freely movable head is impacted. In this type of trauma, there is neither brain lag nor disproportionate distribution of CSF before impact, which accounts for the typical absence of contrecoup contusions. With regard to falls from great heights, the dynamics involving rotation of the body about a fixed point of ground contact associated with a fall from a standing position do not occur. Because gravity produces no torque on a freely falling object, no angular acceleration of the body is produced, and therefore such a fall is a true free-fall state that is associated with an absence of brain lag. For this reason, contrecoup lesions occur infrequently with this type of trauma. One point should be emphasized with regard to the evaluation of coup and contrecoup cortical contusions just described. Displacement of bone associated with skull fracture can contuse the subjacent brain, regardless of the resting or moving status of the head, and such fracture-contusions have nothing to do with the coup-contrecoup mechanisms described. Also, even though the basic mechanisms discussed earlier apply to human beings, they should also be considered when evaluating cerebral contusions of domestic animals, but the situation in human brains is made far more complex because of the numerous wide bony ridges that project into the cranial vault.

Evaluation of spinal cord trauma should include examination not only of the spinal cord but also of the vertebral column and spinal nerve roots. Injuries to the spinal cord can involve concussion, contusion, hemorrhage, laceration, transection, and compression secondary to vertebral trauma and fracture. Contusion in the spinal cord is characterized by vascular tears, hemorrhage, and necrosis. Tears are generally focal and grossly visible. Contusion can occur without fracture of the vertebral column, with fracture, and with fracture plus dislocation of the spinal column. The last-named combination can result in tearing and transection of the spinal cord.

### CENTRAL NERVOUS SYSTEM HEMORRHAGE

Although hemorrhage and hematomas in animal brains can be caused by a wide variety of injuries, trauma to the head is the most common cause. (see [Box 14-8](#) for common causes of brain hemorrhage).

Following trauma to the head, hemorrhages can develop in the epidural, subdural, and subarachnoid space, under the pia mater (subpial), and in the brain ([Fig. 14-97, B](#)). Hemorrhage can be diffuse ([Fig. 14-98](#)) or focal (e.g., hematomas) ([Fig. 14-99](#)). Such hemorrhages can result from sliding of the brain over bony ridges (jugae) within the cranium with resultant stretching and tearing of blood vessels and tissue, and following the cutting and penetration of bone fragments from skull fracture. Cerebral epidural hemorrhage, which is not commonly described in animals, has been reported in the horse, especially jumpers, resulting from falls while working. Epidural hemorrhage does not usually occur because the dura is tightly adhered to the inner surface of the calvarium and there is no epidural space. In trauma causing skull fractures, bleeding from local blood vessels can separate the dura from the calvarium, forming a hematoma in the epidural space.

Subdural hemorrhage, which is an extravasation of blood between the dura mater and arachnoid membrane, occurs in dogs and cats. It is rare and is usually diffuse and does not form hematomas as seen in human beings, where they can be life threatening from compression and herniation of the brain.

942

Subarachnoid and intracerebral hemorrhage are most common in all species following head injury.

943

Hemorrhage can result from injury to the brain with or without a fractured cranium by the mechanisms given previously and also from penetrating objects (bullets and stab wounds).

**Fig. 14-99 Hematoma (arrow), cerebellum, transverse section, dog.**  
Traumatic injury to the head resulted in hemorrhage and the formation of a hematoma from shear, tensile, compressive axial, rotational, and angular forces. (Courtesy Dr. H.B. Gelberg, College of Veterinary Medicine, Oregon State University.)

The same types of hemorrhage that affect the brain (epidural [rare], subdural [rare], leptomeningeal, and parenchymal) also occur in the spinal cord and its meninges. Causes are similar to those for the brain.

14.1.2.7.3.1

### Hematomyelia (Hemorrhagic Myelomalacia)

Traumatic injury to the spinal cord can cause stretching and tearing of blood vessels, usually arterioles, within the gray matter, resulting in hematomyelia. Hematomyelia is also particularly associated with severe type I disk herniation. If larger vessels are torn, blood pressure can force blood into the gray matter. This outcome results in the formation of a dissecting blood-filled cavity ascending and/or descending initially within the gray matter of the spinal cord (Fig. 14-100). This lesion, which is characterized by a softening to semiliquefaction (myelomalacia) and hemorrhage of the tissue, can develop within 12 to 24 hours after injury and can progress both cranially and caudally from the original site of trauma. As the cavity extends cranially, the hemorrhage at the original site also extends into the white matter and can transect the spinal cord. If this lesion extends to the fifth cervical cord segment, the phrenic nerves to the diaphragm will be denervated and respiratory paralysis will result. Bleeding continues until pressure in the blood-filled cavity is equal to the vascular pressure or until

## Pathologic Basis of Veterinary Disease, 4th Edition

bleeding ceases because of hemostasis in the vessel. Hemorrhage can also result from bleeding in arteriovenous malformations within the spinal cord. Hematomyelia is characterized by neurologic deficits consistent with a sudden onset of ascending or descending flaccid paralysis and sensory abnormalities.

**Fig. 14-100 “Duret” hemorrhages, brain stem, transverse section at the level of the pons.** Note the multiple hemorrhages in the periventricular white matter (*arrow*). These hemorrhages are the result of twisting of the brain stem on a longitudinal axis from rotational and axial forces. 14.1.2.7.4

### COMPRESSIVE INJURY

Diseases resulting in compressive injury can affect the brain, spinal cord, or both concurrently. In the brain, diseases such as neoplasia, reticulosis, canine granulomatous meningoencephalitis, and chronic cerebral abscesses can compress adjacent nervous tissue. In the spinal cord, compression can be intramedullary (within the spinal cord) or extramedullary (outside the spinal cord). Causes of intramedullary compression include hemorrhages, neoplasms such as nephroblastoma of the young dog, and chronic expansile inflammatory diseases. Extramedullary compression can be caused by intervertebral disk herniation in the dog, cervical stenotic myelopathy (wobbler syndrome) in the horse and dog, vertebral fracture and dislocation, and neoplasms of the meninges, such as the meningioma; nerve rootlets, such as nerve sheath tumors; or tumor metastasis, such as lymphosarcoma. Finally, developmental anomalies of bone, such as atlanto-occipital malformation and vertebral deformities with hemivertebrae, such as scoliosis, lordosis, and kyphosis (Fig. 14-101), can result in compression of the spinal cord.

943

944

## Pathologic Basis of Veterinary Disease, 4th Edition

Compression of CNS tissue causes neuronal dysfunction by impeding normal anterograde and retrograde axoplasmic flow in axons (Fig. 14-6). In addition, compression of nerves may result in reduced blood flow to nerves and thus also contribute to neuronal dysfunction. Mild compression can result in partial blockage of slow axoplasmic flow and gradual accumulation of neurofilaments and microtubules, which results in mild enlargement of the axon proximal to the compression site, and atrophy of the axon distal to the compression. Eventually, with a long period of time of complete blockage, the distal axon is lost.

14.1.2.7.4.1

Brain Displacements

See Cerebral Edema (Permeability Changes).

### Cervical Stenotic Myelopathy

Cervical stenotic myelopathy, or wobbler syndrome, is characterized by stenosis of the cervical vertebral canal, which causes compressive trauma to the cervical spinal cord (Fig. 14-102). This disease occurs primarily in young rapidly growing large breeds of horses and dogs. Reports indicate that the disease is not caused by a straightforward mechanism but apparently involves several factors (multifactorial disease). For example, stallions that have a genetic predisposition for rapid growth and large body size are reported to be at greater risk of developing the disease. Oversupplementation with protein, vitamins, and minerals used to promote rapid growth may also be another environmental factor in developing cervical stenotic myelopathy.

944

945

Gross and microscopic lesions of the CNS in cervical stenotic myelopathy are similar to the lesions in intervertebral disk herniation. The severity depends on the speed and degree to which the compression is applied and the specific area of the cord that is involved. Central nervous tissue can tolerate a considerable degree of compression if it is applied slowly. Rapid compression can lead to quickly developing hypoxia-ischemia, necrosis, and direct damage to compressed axons. Lesions detected include a spectrum of changes characterized by axonal injury and disruption of myelin sheaths resulting in Wallerian degeneration and necrosis of the gray or white matter or of both. Lesions can be visible grossly from the exterior but are more commonly seen on cross section of the spinal cord.

Microscopically, particularly at the site of injury, there is initial swelling of axons followed after several days by loss of architecture of the CNS as a result of necrosis and a beginning accumulation of gitter cells that have phagocytosed the lipid-rich tissue debris. Eventually the necrotic area is cleared and a cystic space is formed, which is surrounded by varying degrees of astrocytosis and astrogliosis, although not usually prominent unless there is severe destruction. Rostral and caudal to this location, the lesion is primarily one of Wallerian degeneration in the white matter, and the pattern of lesion development seen depends on the level of the spinal cord that is examined relative to the site of compression. At the site of injury, all parts of the white and gray matter of the spinal cord are affected and often necrotic, if the compressive force is sufficient. Rostral to this site, white matter degeneration is generally limited to the ascending tracts in the dorsal funiculi and the superficial portions of the dorsolateral part of the lateral funiculi. Caudal to the area of injury, degeneration is limited to the descending tracts in the ventral funiculi, and the more central portions of the lateral funiculi. It should also be noted that: (1) a lesion may occur at the point of compression because of ischemia, but a lesion can also occur on the opposite side of the compression also because of ischemia that results from compression of the tissue against bone on that side, and (2) Wallerian degeneration can be observed in distal segments of affected axons far from the point of compression within the spinal cord. In the former case, compressive forces can be transferred through the spinal cord to axons and blood vessels away from the contact point, whereas in the latter example degeneration of the distal axon segments can extend for a length of centimeters to meters away from the point of contact.

Cervical stenotic myelopathy has been known for many years to affect horses and more recently has been recognized in the large dog breeds. The disease in the horse has been referred to by several designations: the wobbler syndrome, wobbles, equine incoordination, and more recently, cervical stenotic myelopathy. The disease has been described in many horse breeds.

Cervical stenotic myelopathy in the horse has been divided into two syndromes, referred to as cervical static stenosis and cervical vertebral instability (dynamic stenosis). Cervical static stenosis commonly affects horses 1 to 4 years of age. The spinal cord is compressed at C5 through C7 as the result of an

## Pathologic Basis of Veterinary Disease, 4th Edition

acquired dorsal or dorsolateral narrowing of the spinal canal (Fig. 14-102). The stenosis is due to formation of bone that requires time to develop. The compressive effect with this type of stenosis is present regardless of head position. The second form of cervical stenotic myelopathy (cervical vertebral instability—dynamic stenosis) occurs in horses ranging in age from 8 to 18 months and is characterized by a narrowing of the spinal canal during flexion of the neck, primarily at C3 through C5 vertebrae.

A disease process with many similarities to that in the horse also affects the dog. It has been known as wobbler syndrome, vertebral instability, vertebral subluxation, and cervical spondylolisthesis. The disease has been most frequently described in the Great Dane and Doberman pinscher breeds but has also been reported in the Saint Bernard, Irish setter, fox terrier, basset hound, Rhodesian ridgeback, and Old English sheepdog. Dogs can have signs develop between 8 months and 1 year of age, with a range of 1 month to 9 years. Great Danes tend to have lesions develop at a young age (8 months to 1 year), whereas Doberman pinschers are generally older, often more than 1 year of age. The vertebral and associated spinal cord lesions in the dog have been reported to most often involve the caudal cervical area from C5 through C7 vertebrae. An exception is the basset hound in which C3 is affected.

14.1.2.7.4.3

### Intervertebral Disk Disease

Although the anatomy of vertebrae and intervertebral disks is similar in dogs and human beings, there are notable differences in the anatomy of the spinal cord and spinal nerve roots that result in differences between the two species in clinical signs caused by herniated disks. Disk herniations in human beings commonly occur laterally, rather than dorsally as in dogs, contributing to the differences in clinical presentations (i.e., lateral herniations compress spinal nerve rootlets, whereas dorsal compression in dogs impinges on the spinal cord directly). In human beings the spinal cord terminates at the level of the second lumbar vertebra. Spinal nerve roots forming the cauda equina traverse in the remaining lumbar and sacral vertebrae before they exit the spinal canal to innervate structures. In dogs the spinal cord terminates at the level of the sixth lumbar vertebra, and nerve roots forming the cauda equina traverse in the remaining lumbar, sacral, and coccygeal vertebrae before they exit the spinal canal to innervate structures. Therefore in human beings, disk disease involving the caudal lumbar vertebrae (caudal to L2) results in compression of spinal nerve roots that innervate limbs and are reflected clinically in a condition known as “sciatica” and defined as referred pain in the sciatic nerve. In dogs, herniated disks in the lumbar vertebra primarily compress the spinal cord and under certain circumstances spinal nerves. Dogs thus present clinically with different neurologic signs.

945

946

Differences in clinical signs between dogs and human beings caused by herniated disks arise not only from anatomic differences discussed previously but also from postural differences and the application of shear and stress forces applied to the vertebrae and intervertebral disks. Human beings, with bipedal locomotion and erect posture, dissipate the forces of walking (also running) by transferring these forces from the legs up the vertebral column to the lumbar vertebrae (i.e., first in line to absorb and dissipate forces). In addition, lumbar vertebrae are not stabilized by the rib cage, and thus lumbar vertebrae must also absorb rotational forces (i.e., twisting forces) of motion. Therefore lumbar vertebrae are the primary sites for disk herniation in human beings; however, because of the anatomy discussed earlier, herniated disks compress nerve roots and not the spinal cord. This arrangement results in pain but rarely leg paralysis.

946

947

Dogs, having quadrupedal locomotion and horizontal posture, normally dissipate the forces of walking by transferring these forces up the limbs at right angles to the vertebral column and spinal cord. However, when a dog jumps with downward motion, as an example, from a chair to the floor, the force is directed down the vertebral column and results in greater “end on” compression of disks and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

increased likelihood of herniation. Additionally, thoracic vertebrae are fixed in place by the ribs, and lumbar vertebrae can rotate freely around the axial skeleton. This arrangement directs the impact of stress and shear forces to the thoracolumbar vertebrae and is a primary site of disk herniation and spinal cord compression. In dogs, because the spinal cord is compressed, paralysis of the rear limbs results.

Intervertebral disk disease occurs in the canine species, particularly dogs of the chondrodystrophic breeds typified by the dachshund and Pekingese ([Fig. 14-103](#)). Contiguous vertebrae are held together by the annulus fibrosis of intervertebral disks and dorsal and ventral longitudinal ligaments. This anatomic arrangement results in the spinal canal being properly aligned in an axial plane, so the spinal cord can traverse through the space without compression. Extradural space surrounding the cervical, cranial thoracic, and caudal lumbar spinal cord is sufficient to allow for the accumulation of herniated disk material without substantial compression of the spinal cord. In contrast, there is little extradural space surrounding the thoracolumbar spinal cord and it is the site most likely to have clinically significant disk herniation. As a result in dogs, thoracolumbar disk herniation is often more debilitating than cervical disk herniation.

Fig. 14-103 **Intervertebral disk disease, dog.** **A**, Disk rupture (herniated intervertebral disk), spinal cord compression. Disk material compresses the spinal cord (*arrow*) resulting in Wallerian degeneration. **B**, Vertebral column, lumbar vertebrae. Herniated intervertebral disk (*arrow*) protrudes into the vertebral canal. **C**, Herniated intervertebral disk, spinal cord. The disk material (*arrows*) lies in the epidural space, touches the dura mater, and compresses the overlying spinal cord. An area of necrosis, possibly caused by infarction is present in the ventral area of the left lateral funiculus (*arrowhead*). The multiple small holes in all funiculi are the sites of lost nerves as the result of spinal cord compression, which caused Wallerian degeneration. (**A**, **B**, and **C**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Degeneration of intervertebral disks in chondrodystrophic breeds of dogs is a genetically programmed metaplastic change of the nucleus pulposus, resulting in peripheral to central replacement of the nucleus pulposus with cartilage. It begins as early as 6 months of age, progresses rapidly, and results in the loss of elasticity of the nucleus pulposus. The loss of elasticity places additional mechanical stress forces on the annulus fibrosus, which itself is experiencing degenerative changes similar to those occurring in the nucleus pulposus. The annulus fibrosus is thinnest and thus weakest at its point of contact with the spinal canal. If the annulus fibrosus is ruptured following stress forces placed on the disk by movement, such as jumping downward from a chair, fragments of the nucleus pulposus can be released into the spinal canal (Hansen type I herniation). If the annulus fibrosus ruptures dorsally, fragments compress the ventral funiculi of the spinal cord. If the annulus fibrosus ruptures dorsolaterally to laterally, fragments compress the ventral funiculi, lateral funiculi, and/or spinal nerve roots. Degeneration of intervertebral disks in nonchondrodystrophic breeds of dogs is an aging change of the nucleus pulposus resulting from fibrous metaplasia. This change causes a gradual loss of elasticity of the nucleus pulposus, which may be noticed clinically by 8 to 10 years of age. The gradual loss of elasticity places mechanical stress forces on the annulus fibrosus and results in its protrusion into and compression of the spinal canal (Hansen type II herniation).

Disk herniation causes injury to the CNS by several mechanisms. As discussed previously, the primary injury is caused by the physical trauma of compression and the resulting Wallerian degeneration of affected axons. Additionally, disk material can compress the vascular supply to a spinal cord segment resulting in ischemia, neuronal excitotoxicity, and necrosis. Type I herniation causes the most severe spinal cord damage because there is insufficient time for the spinal cord to compensate and for collateral circulation to develop, as may occur in type II herniation.

14.1.2.7.4.4

### Tumors

In the brain, diseases such as neoplasia cause compression of adjacent nervous tissue. Compression of CNS tissue causes neuronal dysfunction by impeding normal anterograde and retrograde axoplasmic flow in axons. See later discussion of specific types of CNS tumors.

14.1.2.7.5

### LEPTOMENINGEAL HEMORRHAGE

Physical trauma to the CNS will compress, twist, and stretch blood vessels until they are torn. Such injury results in bleeding and leptomeningeal (subarachnoid) hemorrhage ([Fig. 14-98](#)). In the spinal cord, laceration of a large artery or vein can result in prolonged bleeding that ascends or descends the leptomeninges, causing neurologic dysfunction on examination compatible with ascending or descending neurologic deficits in spinal nerve roots.

14.1.2.8

### TUMORS

Neoplasms of the CNS of animals are not as rare as was once believed. In fact, neoplasms occur with a frequency and variety, at least in the dog, similar to those in human beings. The majority of the neoplasms described have been in the dog and cat, and a large portion of these tumors occur in the older population. The intention in discussing CNS neoplasms in this chapter is to present the reader with a brief overview of the more common or better-known neoplasms that occur in animals and is not meant to be all inclusive. The location and characteristics of the primary and common secondary (metastatic) tumors of the nervous system are summarized in [Table 14-12](#).

### EMBRYONAL OR PRIMITIVE NEOPLASMS

Considering the complexities of brain development and the fact that astrocytes and oligodendrocytes arise from common stem cells early in development, it should not be surprising that some neoplasms arising in the CNS have multiple lines of differentiation as indicated by immunohistochemistry. One such neoplasm is the rare primitive neuroectodermal tumor. This neoplasm has recently been recognized by two of the authors in a young calf. An additional report in a primate has been made. Peripheral neuroectodermal tumors are tumors composed of poorly differentiated embryonal cells, tend to occur in young age groups, and are aggressive. Immunohistochemical staining for specific markers confirms multiple lines of differentiation such as neuronal, astrocytic, and oligodendroglial. Typically, one cell type dominates, most commonly neuronal.

Another neoplasm of uncertain histogenesis is the rhabdoid tumor. In human beings this neoplasm most commonly arises in the kidneys and brain and is believed to develop from embryonal stem cells. As is true of other embryonal neoplasms, young individuals are commonly affected. A novel concept is the proposal that these neoplasms arise from primordial stem cells that adopt the phenotypic characteristics of cells in the tissue of origin.

Rhabdoid tumors arising in the brain have cell markers of neuronal or glial differentiation. Neoplasms in the kidneys typically lack these markers. Despite their primary location, cell morphology is similar. The cells are large and round to polyhedral, and cytoplasm is eosinophilic and abundant and contains large inclusions composed of skeins of intermediate filaments. A rhabdoid tumor has been reported in the brain of an 18-month-old dog. Immunohistochemical staining demonstrated that cells distributed throughout the tumor stained for vimentin; however, only scattered cells stained for neuron-specific enolase and GFAP. No cells in the tumor stained for S-100.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 14-12 Primary Tumors of the Nervous System

CENTRAL NERVOUS SYSTEM				
Cell of Origin	Tumor Type	Location	Species Affected	Gross Appearance
Neuron	Medulloblastoma	Cerebellum (WM&GM)	Dog, cow, cat, pig (young animals)	Well-circumscribed, soft, gray to pink expansile mass (usually does not have hemorrhage, cysts, or necrosis)
Oligodendroglia	Oligodendroglioma	Cerebrum, brain stem, interventricular septum (WM&GM)	Dog, cat, cow	Well-demarcated, gray to pink-red, soft or gelatinous expansile mass, usually with areas of hemorrhage
Astroglia	Astrocytoma	Pyramidal lobe, cerebral hemispheres, thalamus, hypothalamus, midbrain, cerebellum, spinal cord (WM&GM)	Dog, cat, cow	Poorly demarcated, firm, gray-white when well differentiated; anaplastic neoplasms are moderately to well demarcated, soft and friable, (usually with areas of necrosis, hemorrhage, edema, and cavitation)
Ependyma	Ependymoma	Ventricular system (lateral; less commonly, third and fourth), central canal of the spinal cord	Dog, cat, cow, horse	Poorly, to moderately, to well-demarcated, soft and gray-white, invasive, destructive gelatinous expansile mass (usually with areas of hemorrhage and cavitation)
Choroid plexus epithelium	Choroid plexus tumor	Ventricular system (fourth; less commonly, third and lateral)	Dog, horse, cow	Well-demarcated, granular to papillary, gray-white to red, expansile
Microglia	Microgliomatosis (reticulosis)	Cerebrum, brain stem	Dog	Poorly demarcated, gray-white, infiltrative mass (may have perivascular pattern)
Endothelium	Hemangiosarcoma	Cerebrum, brain stem	Dog	Well-demarcated, invasive red to dark red, expansile mass

## Pathologic Basis of Veterinary Disease, 4th Edition

Mesothelium (fibroblasts)	Meningioma	Meningeal surface of the CNS (basal cow, sheep areas, convexity and lateral surfaces of cerebral hemispheres, cerebellumtentorium, falx cerebri, surface of the spinal cord)	Cat, dog, horse, cow, sheep	Well-demarcated, variable shapes, firm, encapsulated, and gray-white to soft, red-brown or gray, expansile masses (usually with areas of hemorrhage and necrosis)
Schwann cells (other supportive cells)	Peripheral nerve sheath tumor*	Cranial nerves, spinal nerves (brachial plexus)	Dog, cow, cat	Firm or soft (gelatinous), white or gray, nodular masses
WM&GM, White matter and gray matter.				

\* Other names for this tumor type include: schwannoma, neurofibroma, and neurilemmoma.

14.1.2.8.2

### MEDULLOBLASTOMA

This neoplasm has characteristics similar to the less frequently occurring neuroblastoma, and both are considered to arise from cells of the neuronal lineage. The cell of origin for the medulloblastoma has not been definitely determined, but it has been proposed that the neoplasm can arise from primitive cells originating in the neuroepithelial roof of the fourth ventricle and that give rise to the external granular cell layer.

948

949

In animals, medulloblastomas have been reported in dogs, cats, cows, and pigs. There is a predilection for these tumors in young animals. The neoplasm chiefly occurs in the cerebellum of puppies and calves and sometimes also in adult dogs. The neoplasm is well circumscribed, soft, gray to pink, and usually does not have hemorrhages, cysts, or necrosis. The growth can compress the fourth ventricle and cause an obstructive hydrocephalus and can infiltrate adjacent structures including the leptomeninges. It can metastasize through the CSF in the ventricles or subarachnoid space. Microscopically the neoplasm is highly cellular and consists of round to elongated nuclei that have prominent chromatin in an ill-defined cytoplasm. The cells are arranged in sheets or broad bands and also can form pseudorosettes. Mitoses can be numerous.

14.1.2.8.3

### ASTROCYTOMAS

Astrocytomas have been morphologically classified based on their degree of differentiation (histologic features in H&E stained sections) and include the following three types: diffuse astrocytomas, anaplastic astrocytomas, and glioblastoma multiforme. The degree of differentiation refers to how closely astrocytes forming the tumor resemble normal astrocytes within the CNS. Diffuse astrocytomas tend to have the most well-differentiated astrocytes, whereas glioblastoma multiforme has the most poorly differentiated astrocytes. All of these tumors are malignant; however, the degree of malignancy is often inversely related to the degree of differentiation.

Astrocytomas have been reported in dogs, cats, and cattle but are most frequently diagnosed in dogs (10% incidence) and uncommon in the cat. Brachycephalic breeds such as Boston terriers and boxers and dogs 5 to 11 years of age are most commonly affected. Common sites include the cerebral hemispheres, especially the temporal and pyriform lobes, thalamus-hypothalamus, midbrain, and less frequently, the cerebellum and spinal cord.

## Pathologic Basis of Veterinary Disease, 4th Edition

Astrocytomas will often displace normal tissue; however, their gross appearance often depends on their rate of growth and degree of differentiation (Fig. 14-104). Slow-growing, well-differentiated astrocytomas (less malignant) are usually difficult to distinguish from normal tissue and are rather solid or firm and gray-white. Rapidly growing, poorly differentiated astrocytomas are more malignant and are easier to discern because they have areas of necrosis, hemorrhage, cavitation, and edema.

Microscopically the more well-differentiated diffuse astrocytomas consist of a rather uniform cell type loosely organized. Cell size varies, and distinct ramifying cytoplasmic processes can be observed. Nuclei vary in size and shape and contain more chromatin than normal astrocytes. Cells tend to be arranged around and along blood vessels. The boundary between neoplastic and normal tissue is indistinct. Anaplastic astrocytomas and glioblastoma multiforme have extreme cellular pleomorphism often with giant cell formation.

**Fig. 14-104 Astrocytoma, brain, transverse section at the level of the thalamus, dog.** The deep ventromedial area (thalamus/hypothalamus) of the right hemisphere (*arrows*) contains a poorly demarcated, nonencapsulated, expansile mass, which is a space-occupying lesion that has displaced the midline to the left and compressed the right lateral ventricle. The left lateral ventricle is mildly dilated, most likely from compression of the interventricular foramen. (*Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

Increasing usage of immunohistochemical markers for glial cells and indicators of cellular proliferation will undoubtedly enhance the specificity and prognostic significance of the diagnosis of different glial cell neoplasms in animals. The most reliable marker for astrocytomas is GFAP, although vimentin has proved useful in some cases.

## Pathologic Basis of Veterinary Disease, 4th Edition

Clinical signs in animals with astrocytomas vary depending on the location of the tumor in the CNS but can include behavioral changes, ataxia, tetraparesis, seizures, circling, and abnormal cranial nerve and proprioceptive reflexes.

14.1.2.8.4

### CHOROID PLEXUS PAPILLOMAS AND CARCINOMAS

Choroid plexus papilloma occurs most commonly in the dog but has been reported in the horse and in cattle. There is no breed predilection in dogs. In the dog, the neoplasm occurs most frequently in the fourth ventricle, but it also can be located in the third and lateral ventricles.

Grossly the neoplasm is a well-defined, expansive, granular to papillary growth located within the ventricular system that is gray-white to red and compresses the adjacent nervous tissue (Fig. 14-105). 949

Noncommunicating hydrocephalus may result from obstruction of CSF flow within the ventricular system. Microscopically these neoplasms generally resemble the choroid plexus and are characterized by an arborizing vascular connective tissue stroma that is covered with a cuboidal to columnar epithelial layer. Mitoses are not present in the benign form. A more malignant variety, choroid plexus carcinoma, is characterized by invasiveness, presence of mitoses, additional occurrence of solid tumor growth, and a tendency to metastasize within the ventricular system, or into the subarachnoid space (through the lateral apertures), where implantation in the ependyma or meninges, respectively, occurs. Currently there are no reliable immunohistochemical markers for these tumors. 950

**Fig. 14-105 Choroid plexus tumor (carcinoma), brain, sagittal section, dog.** The third ventricle contains an expansile mass (*arrow*) that has invaded the normal tissue ventral to it. The mass ventral to the medulla (*right*) may be a metastasis arising from tumor cells that entered the third ventricle and then spread in the cerebrospinal fluid caudally, through the mesencephalic duct, into the fourth ventricle, and out through a lateral aperture into the subarachnoid space. (Courtesy Dr. Y. Niyo, College of Veterinary Medicine, Iowa State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

The age range of dogs with choroid plexus tumors in one study was 5 to 13 years, except for one dog that was 2 years of age. Clinical signs in animals with choroid plexus tumors vary depending on the location of the tumor in the CNS but can include behavioral changes, ataxia, paresis, seizures, circling, and abnormal cranial nerve and proprioceptive reflexes. 950 951

14.1.2.8.5

### EPENDYMOMAS

Ependymomas are one of the less frequently occurring neoplasms in dogs, cats, cattle, and horses. Some reports on the dog indicate a higher frequency in brachycephalic breeds. Ependymomas usually involve the lateral or, less commonly, third and fourth ventricles. They also occur in the central canal of the spinal cord. The neoplasm can be observed within the ventricular system and subarachnoid space, likely attributable to local metastasis via the CSF. Noncommunicating hydrocephalus may result from obstruction of CSF flow within the ventricular system.

**Fig. 14-106 Ependymoma, brain, transverse section at the level of the hippocampus, dog.** The third ventricle contains a moderately well-demarcated expansile mass (*arrows*) that has invaded normal tissue ventral to it. Moderate hydrocephalus is present in both lateral ventricles from blockage of the third ventricle. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Grossly, ependymomas are usually large expansile intraventricular masses with generally well-demarcated margins (Fig. 14-106). The neoplasm is soft and gray-white to red depending on blood content and has a smooth cut surface in dogs. In cats the cut surface can be granular in texture. In some ependymomas the cut surface may have gelatinous consistency and be cavitated. More aggressive tumors show invasion into the normal tissue at its margins. Microscopically, ependymomas are highly cellular and well vascularized.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Cells have hyperchromic, round to oval nuclei with scant or undetectable cytoplasm. Cells form perivascular rosettes (pseudorosettes) with nuclear polarity away from the vessel wall. Cells are also arranged in sheets and bands. The mitotic rate is variable. Hemorrhage, mucinous and cystic degeneration, and capillary proliferation occur. Malignancy is indicated by invasive growth, frequent mitoses, and anaplasia. Currently there are no reliable immunohistochemical markers for ependymomas.

The average age of affected dogs ranges from 6 to 12 years. Occurrences in a cat as young as 18 months old and in a calf 5 months old have been reported. Clinical signs in animals with ependymomas vary depending on the location of the tumor in the CNS but can include behavioral changes, ataxia, paresis, seizures, circling, and abnormal cranial nerve and proprioceptive reflexes.

14.1.2.8.6

### OLIGODENDROGLIOMAS

Neoplasms composed of oligodendrocytes occur most commonly in the dog, but cases have been reported in cats and cattle. The reported incidence varies; some reports indicate oligodendrogliomas as the most common neuroectodermal neoplasm (5% to 12% incidence), whereas others place it second to astroglial neoplasms. As with astrocytomas in dogs, there is a predilection for brachycephalic breeds (Boston terriers, boxers, and bulldogs), and the age range is the same as for astrocytomas (5 to 11 years of age). Neoplasms occur in all areas of the white matter of the cerebrum, brain stem, and interventricular septum ([Fig. 14-107](#)). Neoplasms tend to extend to meningeal and ventricular surfaces, but dissemination in the CSF is uncommon.

Grossly, most oligodendrogliomas can be relatively well demarcated from surrounding tissue or their margins can be indistinct and blend in with adjacent normal white matter. The neoplasms vary in size, can grow quite large, are gray to pink-red, and are soft or gelatinous with areas of hemorrhage. In larger tumors the central area may be cystic. Microscopically the neoplasms are composed of densely packed cells. Nuclei are centrally located, hyperchromic, and surrounded by pale or nonstaining cytoplasm creating a perinuclear halo. Other patterns include cells arranged in rows, especially peripherally, or in semicircles. Mitoses are generally infrequent. Regressive changes include mucoid degeneration, edema, cavitation, and rarely mineralization. Extensive necrosis is uncommon. Currently there are no reliable immunohistochemical markers for oligodendrogliomas.

**Fig. 14-107 Oligodendroglioma, brain, cerebellum, transverse section caudal to the pons, dog.** The tumor is relatively well demarcated from the surrounding cerebellum. Oligodendrogliomas may be well demarcated or merge with adjacent normal brain. They vary in size, are gray to pink-red, and are soft or gelatinous with areas of hemorrhage (*arrow*). (Courtesy Dr. W. Crowell, College of Veterinary Medicine, University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

### 14.1.2.8.7

#### MENINGIOMAS

Meningioma is the most common mesodermal neoplasm of the CNS of animals, especially in cats. Sites of occurrence in the dog include the basal area of the brain, the area over the convexity of the cerebral hemispheres, the cerebellum-tentorium area, the lateral surface of the brain, the falx cerebri, and the surface of the spinal cord. Retrobulbar involvement (originating from the optic nerve sheath) also occurs. In the cat, the neoplasm uniquely occurs in the tela choroidea of the third ventricle but also occurs over the cerebral hemispheres, along the falx cerebri, over the cerebellum and tentorium, and rarely at the base of the brain. Occurrence in the meninges of the spinal cord is not common. Meningiomas have been reported to arise from arachnoid “cap cells,” which are on the external surface of the arachnoid membrane. These cells cover the surface of the arachnoid layer that oppose the surface layer of the dura mater, and thus these tumors project into the subdural space and often into the CNS parenchyma.

Grossly, neoplasms in the dog are solitary and vary in size. The neoplasms are well defined, spherical, lobulated, lenticular, or plaquelike in shape; firm; encapsulated; and gray-white (Fig. 14-108). Sometimes on the cut surface there are soft, red, brown, or gray areas of hemorrhage and necrosis. Because these

## Pathologic Basis of Veterinary Disease, 4th Edition

---

neoplasms grow slowly, they cause pressure atrophy of the adjacent nervous tissue. Meningiomas can be invasive, and sometimes there is hyperostosis of the overlying bone. In the cat, meningiomas vary in size from barely detectable to 2 cm in diameter. Cats, and occasionally cattle, can have more than one neoplasm. Other characteristics are comparable with those described in the dog.

Microscopically, several patterns of neoplastic cells can occur, and more than one can be present in a given neoplasm. Based on their cytomorphologic features, these tumors are grouped into one of six categories: (1) epithelioid/meningotheliomatous; (2) fibroblastic; (3) transitional (features of both epithelioid and fibroblastic); (4) psammomatous; (5) angioblastic; and (6) anaplastic/malignant.

Cytomorphologic features are beyond the scope of this chapter; however, the more common pattern is characterized by the formation of nests, islands, or laminated whorls of cells. The cells have large cell

951

---

bodies with abundant cytoplasm, ill-defined cell boundaries, and elongated, oval, open nuclei with

952

peripherally located chromatin. The number of cells making up a whorl can vary from a few to many, and in the center of such structures can be mineralized material (referred to as psammoma bodies). A second pattern is characterized by strands or streams of elongated cells with a rather irregular or parallel orientation. Regressive changes include hemorrhage and cavernous vascular formations. Invasive growth occurs but is less common than growth by expansion. Currently vimentin and pancytokeratin may be useful immunohistochemical markers for these tumors.

Fig. 14-108 **Meningioma, cat, brain.** **A**, On the surface of the right parietal cortex is a mass (*arrows*) that has compressed and distorted the adjacent parenchyma. It is a space-occupying lesion that has displaced the midline (cerebral longitudinal fissure) to the left. **B**, Transverse section at the level of the hippocampus of the brain depicted in Fig. 14-108, **A**. The tumor has compressed the right cerebral hemisphere and this has resulted in the midline being displaced to the left with compression of the left cerebral hemisphere. The meningioma does not invade the brain and can be “shelled” out at necropsy or surgery. (**A** and **B**, Courtesy College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Meningiomas occur most frequently in the dog and cat but have been reported in other species of domestic animals including horses, cattle, and sheep. In the dog, this neoplasm occurs in several breeds, with dolichocephalic animals being frequently represented. The majority of meningiomas are in dogs between 7 and 14 years of age and in cats 10 years old or older.

Other benign neoplasms of mesenchymal origin, such as neurofibromas of spinal cord nerve roots, occur in the meninges. Spindle cell sarcomas, such as neurofibrosarcomas and dural osteosarcomas, have also been reported in the meninges.

14.1.2.8.8

### MICROGLIOMATOSIS

Microgliomatosis, which has been classified as a proliferative neoplastic disease, has some features that are quite distinct from the inflammatory and neoplastic forms of reticulosis described in an earlier section (see Reticulosis/Granulomatous Meningoencephalitis). Gross lesions are usually not present. The cells, which infiltrate the CNS without topographic perivascular arrangement, resemble microglia in that their nuclei, which vary in size and shape and have prominent chromatin, are the only visible cellular component following conventional staining. Also, mitoses can be common, and there is no accompanying reticulin fiber formation such as occurs in the inflammatory and neoplastic reticuloses. Microgliomatosis occurs in older dogs.

14.1.2.8.9

### HEMANGIOSARCOMA

Primary hemangiosarcoma of the CNS is a rare neoplasm arising from endothelial cells. The disease is most common in dogs but can occur in all domestic species. The neoplasm is a solitary expansile red to dark red mass within the cerebral cortex. Its color and bloody consistency are helpful in differentiating it from a primary or metastatic melanoma. Most hemangiosarcomas found in the CNS are from metastases.

14.1.2.8.10

### METASTATIC TUMORS

Hematogenously metastasizing neoplasms occur and affect the brain more often than the spinal cord. The species in which metastasis has been most commonly reported is the dog; the next most frequent is the cat. Of the metastasizing carcinomas, mammary gland carcinoma in the dog has been reported to occur most frequently, although others have been described. Hemangiosarcoma of the heart, liver, and spleen is one of the most common metastasizing sarcomas in the dog; others are the mesenchymal component of the malignant mixed mammary gland tumor, lymphosarcoma, fibrosarcoma, and malignant melanoma. In the CNS, metastatic hemangiosarcomas appear to have predilection for the gray matter–white matter interface (Fig. 14-109). In the cat, the neoplasms that metastasize to the CNS include the mammary gland carcinoma (Fig. 14-110) and lymphosarcoma. Primary CNS lymphomas have been reported.

952

953

**Fig. 14-109 Hemangiosarcoma, metastatic, brain, formalin-fixed, transverse section at the level of the thalamus, dog.** Note the prominent hematogenous metastases, which appear as black nodules of various sizes distributed throughout the brain, sometimes at the gray matter–white matter interface. In an unfixed (fresh) specimen, the nodules would be red to dark red from erythrocytes. Black nodules in a fresh specimen would be consistent with metastatic melanoma. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 14-110 Mammary carcinoma, metastatic, brain, transverse section at the level of the hippocampus, dog.** The right cerebral hemisphere contains a well-demarcated mass (*arrow*), which has caused enlargement of the right cerebral hemisphere and compression of the right lateral ventricle. The left lateral ventricle is slightly dilated, probably because of pressure on the interventricular foramen. (*Courtesy Drs. F. Moore and J. Carpenter, Angell Memorial Animal Hospital; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.*)

### 14.2 Peripheral Nervous System

#### 14.2.1 INTRODUCTION

##### 14.2.1.1 ORGANIZATION

During the last few years, there have been important changes in the approach and terminology used to categorize diseases that involve that portion of the nervous system outside of the CNS. The traditional approach divided these diseases into those of the PNS and the autonomic nervous system (ANS). Advances in neuroscience have resulted in the PNS being divided into three divisions: the sensorimotor division (formerly the PNS), the autonomic division (formerly the ANS), and the enteric division (a newly labeled system). The sensorimotor division is formed by sensory neurons (afferent components of cranial and spinal nerves, sensory receptors, and cranial and spinal ganglia) and motor neurons (efferent components of cranial and spinal nerves, and lower motor neurons) that innervate skeletal muscle via myoneural junctions ([Fig.](#)

## Pathologic Basis of Veterinary Disease, 4th Edition

14-111). The autonomic and enteric divisions consist of networks of afferent and efferent nerves and their ganglia (Meissner's [submucosal] and Auerbach's [myenteric] plexuses) that regulate, as examples, the contractility and relaxation of smooth muscle of the vascular and alimentary (peristalsis) systems and glandular secretions via sympathetic and parasympathetic fibers. Afferent and efferent nerve fibers of the autonomic and enteric divisions are carried in the afferent and efferent branches of the sensorimotor division (cranial and spinal nerves).

Peripheral nerves are composed of groups of axons, both myelinated and nonmyelinated, and of varying caliber (Fig. 14-112). As with the CNS, conspicuous components of axons are neurofilaments and microtubules. Neurofilaments provide structural support; microtubules are intimately involved in bidirectional axoplasmic flow of structural components, nutrients, and trophic factors to and from the cell body required for maintenance of the axons and neuronal integrity. Transport from the neuron cell body to the distal axon (anterograde flow) occurs at fast (400 mm per day or about 0.25 mm per minute) and slow (1 to 4 mm per day) rates. Retrograde transport from the distal axon to the cell body progresses at a rate of 200 mm per day (about 0.125 mm per minute).

953

Supporting cells in the PNS include Schwann cells and fibroblasts of the endoneurium and the satellite cells (Schwann cell–like cells) of the dorsal root ganglion. Schwann cells surround both myelinated and nonmyelinated axons and are responsible for formation of the myelin sheaths (Fig. 14-112). In contrast to the CNS, where one oligodendroglial cell can send out numerous processes to myelinate many different axonal internodes of several different axons, one Schwann cell myelinates one internode of one axon. As a result, the entire length of an axon in the PNS is myelinated by many individual Schwann cells.

954

Although Schwann cells do not appear to play a role in axon guidance during formation of the PNS, these cells are necessary for maintenance of axons and secrete neurotrophic factors that play a role in regeneration. Axons are grouped into fascicles along with surrounding loosely organized tissue fibrils and specialized endoneurial fibroblastic cells with phagocytic capabilities (Fig. 14-112). When an axon is damaged so badly as to cause Wallerian degeneration, removal of the debris is by these putative endogenous phagocytic cells, augmented by an influx of blood monocytes. Mast cells and small blood vessels also are present among the nerve fibers.

**Fig. 14-111 Myoneural junctions.** Peripheral nerve with terminal axons ending at myoneural junctions on muscle fibers (*arrow*). Dissected and glycerol-mounted muscle fibers. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 14-112 Organization of a peripheral nerve, sensory, and motor branches and their coverings.** In human (bipeds) neuroanatomy, spinal nerve rootlets are termed anterior and posterior rather than ventral and dorsal, respectively, in animals. (From McCance KL, Huether SE: Pathophysiology: the biologic basis for disease in adults & children, ed 4, St Louis, 2002, Mosby.)

Depending on species and anatomic location, endothelial cells of endoneurial blood vessels can be joined by tight junctions preventing free passage of some macromolecules and providing an incomplete blood-nerve barrier. Collagen bundles and modified fibroblastic cells, termed perineurial cells, form the perineurium that ensheathes individual nerve fascicles. The perineurium contributes some barrier properties by preventing the free diffusion of macromolecules into the nerve fascicles. The fibrous epineurium is continuous with the dura mater as a peripheral nerve joins the CNS and encloses groups of nerve fascicles. The epineurium contains fibroblasts, mast cells, and adipocytes, the latter probably providing some protection to the nerve. Satellite cells are found in dorsal root ganglia within the matrix formed by the endoneurium that envelops cell bodies of peripheral nerves. They function in a supportive, nonmyelinating role, much like perineuronal oligodendroglia in the CNS.

The autonomic and enteric divisions of the PNS function primarily to transmit impulses from the CNS to peripheral organs (efferent nerves) that regulate (involuntary control) the function of these organ systems (heart, vascular system, visceral smooth muscle, and exocrine and endocrine glands). These effects include but are not limited to the rate and force of contraction and relaxation in smooth (visceral organs and blood vessels) and striated muscle (heart). Afferent nerves, which transmit from the periphery to the CNS, mediate visceral sensation and vasomotor and respiratory reflexes through baroreceptors and chemoreceptors in the carotid sinus and aortic arch. Autonomic and enteric functions are regulated in the medulla, pons, and hypothalamus of the CNS.

954

955

The autonomic division has two structural and functional components: the sympathetic and parasympathetic systems. These systems usually have opposing effects on innervated organ systems. The parasympathetic system acts, as examples, to lessen the effects of increased vasoconstriction (smooth muscle) and contractility (heart rate) exerted by the sympathetic system.

The enteric division of the PNS system exerts effects on digestive processes such as motility, secretion and absorption, and blood flow. The main components of the enteric nervous system are myenteric plexuses

## Pathologic Basis of Veterinary Disease, 4th Edition

---

(Auerbach's plexuses), located between the longitudinal and circular layers of muscle, and submucosal plexuses (Meissner's plexuses) that innervate esophageal and intestinal smooth muscle. Injury to these plexuses can lead to dysautonomias, which are discussed in a later section.

### 14.2.1.2 BARRIER SYSTEMS

#### 14.2.1.2.1 BLOOD-NERVE BARRIER

The blood-nerve barrier regulates the free movement of certain substances from the blood to the endoneurium of peripheral nerves. Barrier properties are conferred by tight junctions between endothelial cells of the capillaries of the endoneurium and perineurium, and by selective transport systems in the endothelial cells.

### 14.2.1.3 RESPONSES OF THE AXON TO INJURY

See under Central Nervous System: Responses of Neurons to Injury and Wallerian Degeneration and Central Chromatolysis.

### 14.2.2 DISEASES

#### 14.2.2.1 PERIPHERAL NEURONOPATHIES AND MYELINOPATHIES

Many disorders affecting the CNS are also manifested in lesions in the PNS, either: (1) because of damage to neuron cell bodies of lower motor neurons residing in the CNS or (2) because the PNS is equally vulnerable to the disease. As an example in the first case, in lysosomal storage diseases substrate accumulates in cell bodies of lower motor neurons. Cell death and axonal degeneration of the PNS are the end points of a chronic and progressive process of substrate accumulation that interferes with cellular biochemical processes and transport systems. In the second case, substrate will also accumulate in cell bodies of sensory neurons located in the dorsal root ganglion of the PNS, resulting in cell death and axonal degeneration. Despite this caveat, there are certain diseases that primarily affect the PNS. Depending on whether the lesion is in a sensory or motor nerve or both, diseases of the PNS can manifest clinically as motor disturbance, sensory deprivation, or a combination of motor and sensory alterations. Space constraints do not allow an exhaustive coverage of disorders of the PNS. Many of the reported disorders seem to represent isolated occurrences in a specific breed. This section will cover the major types of PNS diseases with reference to specific disorders for illustrative purposes.

##### 14.2.2.1.1 CONGENITAL/HEREDITARY/FAMILIAL DISEASES

Primary sensory neuropathies Included here are the hereditary, familial, and breed- or species-associated syndromes reported in a variety of domestic animals that result in degeneration of PNS sensory neurons (dorsal root ganglion) or axons innervating the limbs. Two examples of primary sensory neuropathies have been described in English pointers and long-haired dachshunds. In pointer dogs, the onset is 2 to 12 months of age with signs of self-mutilation and insensitivity to pain resulting in neuropododermatitis or acral mutilation syndrome ([Fig. 14-113](#)). Additional signs can include ataxia, loss of conscious proprioception, and patellar hyporeflexia. In dachshunds, a sensory neuropathy is manifested shortly after birth by ataxia and alterations in the function of the autonomic division of the PNS, such as urinary

## Pathologic Basis of Veterinary Disease, 4th Edition

incontinence and digestive disturbances. Lesions in pointer dogs consist of small dorsal root ganglia with neuronal loss and replacement by satellite cells (nodules of Nageotte) and mild reduction in size of dorsal nerve rootlets, because of degeneration and loss of myelinated and nonmyelinated axons with the presence of cell bands of Büngner (indicative of attempts at remyelination). In dachshunds, lesions are a distal axonopathy with loss of large myelinated and unmyelinated axons. Lesions can occur in the vagus nerve.

Other degenerative distal axonopathies of the PNS have also been reported in Birman cats and in dog breeds, including Bouvier des Flandres, Siberian huskies and crossbreeds, Boxer dogs (sensory axonopathy), rottweilers (sensory axonopathy), dachshunds (sensory axonopathy), Dobermans (dancing Doberman disease—thought to be a primary myopathy), German shepherds (giant axonal neuropathy), and Dalmatians. They may have a genetic basis and be inherited.

955

956

### Fig. 14-113 Neuropododermatitis (acral mutilation syndrome), dog.

This disorder, a primary sensory peripheral neuronopathy with self-mutilation and insensitivity to pain, is caused by the absence of (or small) dorsal root ganglia, reduction in size of dorsal nerve rootlets, and degeneration and loss of myelinated and nonmyelinated sensory axons. This dog wore off its footpads when placed on a concrete run. Satellite cell proliferation is commonly present in other large autonomic ganglia, (i.e., celiac ganglion). (Courtesy College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Gross lesions in the PNS are inapparent; however, microscopically, depending on the breed involved, spheroids can be found in cranial and spinal nerves and brain stem nuclei. Affected animals are usually young (birth to 15 months of age) and show signs of ataxia, muscle weakness (paresis and tetraparesis) followed by muscle atrophy, proprioceptive deficits, urinary incontinence, and digestive disturbances (enteric division involvement).

### 14.2.2.1.1.1

#### Colonic Agangliosis

Colonic agangliosis (lethal white foal syndrome) is a disorder involving development of the enteric division of the PNS and is analogous to Hirschsprung's disease in infants. This disease occurs most commonly in foals of American Paint Horses with Overo markings. Affected foals have white or nearly white skin color. Specific information on these skin marking patterns can be obtained from the American Paint Horse Association. The gene, which results in the "colonic agangliosis" phenotype being expressed, is inherited as a homozygous dominant.

Recently, mutations in the endothelin- $\beta$  receptor gene have been detected in affected horses and in some patients with Hirschsprung's disease. Both glial-derived neurotrophic factor (GDNF) and endothelin-3 (ET-3) are required for normal development of the enteric nervous system and enteric ganglia. It is proposed that GDNF is required for proliferation and differentiation of neuronal precursor cells destined to populate the gut. ET-3 might modulate these effects by inhibiting differentiation, thus allowing sufficient time for precursor cells to migrate and populate the intestinal wall in a cranial to caudal progression before they differentiate to form enteric ganglia.

There are no gross lesions in the intestine related to the enteric division of the PNS. Microscopically the myenteric and submucosal enteric ganglia are absent and the areas affected vary but can extend anywhere between the ileum and distal large colon. Affected foals die soon after birth from functional blockage of the ileum and/or colon because of the lack of innervation and thus normal gut motility.

### 14.2.2.1.1.2

#### Hypomyelination/Dysmyelination Diseases

In contrast to the CNS, congenital and postnatal disorders of myelin formation are rare in the PNS but have been described in dogs, calves, and a cat. These disorders are thought to have a genetic predisposition and to be inherited. In dogs, hypomyelination has been described in golden retrievers with onset at approximately 7 weeks of age. Clinical signs include a peculiar hopping gait, depressed spinal reflexes, and circumduction of the limbs while walking. Lesions in peripheral nerves include thin myelin sheaths, increased numbers of Schwann cells, neurolemma cells with abnormally increased cytoplasmic volume, and no evidence of active demyelination or effective remyelination. The lesions are believed to involve a defect in Schwann cells or an abnormal axon-Schwann cell interaction.

In calves a myelinopathic peripheral neuropathy has been described in Santa Gertrudis-Brahman cross-breeds. Microscopically, lesions were present in the vagus nerves, somatic peripheral nerves of the brachial plexuses, and the sciatic nerves. Dorsal and ventral spinal nerve roots also had similar lesions. There was "sausage-shaped" thickening of the myelin sheaths as a result of excess myelin arranged about the axons or as irregularly folded myelin sheaths not surrounding axons. Onset of clinical signs was at 6 to 10 months of age. Clinical signs were dysphagia, abnormal rumination with bloat, and a weak shuffling gait. Congenital hypomyelination has also been described in a 2-month-old Dorsett lamb with tremors and incoordination.

### DEMYELINATION DISEASES

A variety of injuries similar to those described in the CNS can cause primary demyelination in the PNS. 956

Specific demyelinating diseases are covered in the following section. In response to injury, Schwann cells can proliferate to restore the myelin sheaths, often forming longitudinal columns along the course of a degenerated axon termed cell bands of Büngner. Remyelination results in internodes that are shorter than the internodes of adjacent normal myelinated axons, and this change is used microscopically to detect areas of remyelination in peripheral nerves. Another lesion that occurs with repeated episodes of demyelination is proliferation of Schwann cell processes forming concentric whirls, called onion bulbs, that surround the axon. 957

### Acute Idiopathic Polyneuritis

Acute idiopathic polyneuritis (coonhound paralysis) is an acute, fulminating polyradiculoneuritis with ascending paralysis that occurs in dogs after the bite or scratch of a raccoon. By definition, *polyradiculitis* refers to disease or injury involving multiple cranial or spinal nerve roots, whereas *polyradiculoneuritis* refers to disease or injury involving multiple cranial or spinal nerve roots and their corresponding peripheral nerves.

Coonhound paralysis has been compared with Guillain-Barré syndrome. This human syndrome typically follows a viral illness, vaccination, or some other antecedent disease that results in an autoimmune response resulting in primary demyelination of cranial and spinal rootlets and nerves and delayed conduction of action potentials down the axon. Humoral and cell-mediated components are suspected to be involved in the autoimmune response.

Coonhound paralysis, like Guillain-Barré syndrome, is believed to represent an autoimmune primary demyelination. Despite the lack of close association of macrophages with the degenerating myelin and axons early in the development of the lesions, secretion of TNF- $\alpha$  by these cells could explain both the demyelination and axonal degeneration.

Acute idiopathic polyneuritis has been reported in dogs without an association with raccoons and also occurs rarely in cats, suggesting multiple factors might be involved in this type of nerve damage. Lesions in coonhound paralysis are most severe in ventral spinal nerve rootlets and progressively diminish distally in the peripheral nerve. Involvement of dorsal spinal nerve rootlets and ganglia is not constant and relatively minor. Lesions in the ventral nerve rootlets consist of segmental demyelination with a variable influx of neutrophils, depending on the acuteness and severity of clinical signs, along with lymphocytes, plasma cells, and macrophages (Fig. 14-114). Axonal degeneration is a common sequela. Evidence of remyelination with cell bands of Büngner and axonal sprouting occur during the recovery phase, but the effectiveness of the latter to establish continuity of the nerve rootlet and thus reinnervation of muscle is limited.

**Fig. 14-114 Polyradiculoneuritis, coonhound paralysis, peripheral nerve, dog.** This disease is thought to result from an autoimmune response leading to primary demyelination of cranial and spinal rootlets and nerves. Myelin sheaths in this peripheral nerve are distended and fragmented along their length (*arrowheads*) and have been infiltrated by a mixed population of inflammatory cells consisting of lymphocytes, macrophages (1), and plasma cells (2). Enlarged spaces in the myelin sheath, termed digestion chambers (*arrows*), which form in response to inflammatory and degradative processes, contain myelin debris and macrophages (not shown in this example). Axonal degeneration can occur secondary to primary demyelination. H&E stain. (Courtesy Drs. R.M. Doty, J.J. Andrews, and J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

A chronic polyradiculoneuritis with infiltrations of lymphocytes, plasma cells, or macrophages; demyelination; and variable axonal degeneration in cranial and spinal nerve rootlets and cranial nerves is also reported in dogs and cats. With repeated episodes of demyelination, onion bulbs can be apparent. Both sensory and motor nerves can be involved with sensory disturbances and muscle atrophy.

Clinically, affected dogs have signs of coonhound paralysis develop 1 to 2 weeks after exposure to raccoon saliva. Initial signs of hyperesthesia, weakness, and ataxia are replaced in 1 to 2 days by tetraparesis and/or tetraparalysis that may last from weeks to months. Dogs can die from respiratory paralysis. Recovery is common, but can be prolonged in dogs with extensive muscular atrophy.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

14.2.2.1.2.2

### Canine Inherited Hypertrophic Polyneuropathy

Canine inherited hypertrophic polyneuropathy is a familial disorder in Tibetan mastiffs. The primary defect is in the Schwann cells, but the pathogenesis is undetermined. There are no gross lesions in the PNS. Microscopic lesions consist of demyelination with onion bulb formation. The Schwann cell's cytoplasm is distended by accumulations of actin filaments. Axonal degeneration occurs but is mild.

957

958

Clinical signs in canine inherited hypertrophic polyneuropathy begin at 7 to 10 weeks of age. They include pelvic limb muscle weakness, depressed spinal reflexes, and muscle atrophy that later progress to involve forelimbs and eventually cause recumbency. Neuropathies with primary developmental demyelination have also been reported in Alaskan malamutes and in beagle-basset hound crosses. A hypertrophic polyneuropathy has rarely been reported in unrelated domestic cats with onset at approximately 1 year of age.

14.2.2.1.2.3

### Coyotillosis

Another cause of primary demyelination is the shrub coyotillo (*Karwinskia humboldtiana*) affecting mainly small ruminants in the semidesert areas of the southwest United States. Seeds in the fruit contain polyphenolic compounds that when ingested are toxic. Four toxic compounds have been isolated, including a substance called karwinol A that induces primary demyelination of peripheral nerves.

14.2.2.1.3

### DYSAUTONOMIAS

14.2.2.1.3.1

#### Hereditary Dysautonomias

Dysautonomia is a degeneration of neurons in the ganglia of the enteric division of the PNS that has been reported in dogs, cats (Key-Gaskell syndrome), a llama, sheep, and horses. The cause is unknown, and a hereditary basis is suspected in some cases. A toxic cause has been postulated in the cat. Lesions recently reported in sheep with abomasal emptying defect resemble those reported in dysautonomic diseases of humans and other animals.

Lesions are observed in peripheral and enteric (autonomic) ganglia and vary from neuronal chromatolysis and nuclear pyknosis in more acute cases to loss of neurons and proliferation of satellite cells in cases with longer duration (Fig. 14-115). Minimal to mild leukocytic infiltrates occur, but the lesions are not overtly inflammatory in nature. In cats and dogs, clinical signs are varied and include gastrointestinal disturbances, urinary incontinence, mydriasis, unresponsive pupils, bradycardia, and other signs associated with autonomic dysfunction.

14.2.2.1.3.2

#### Acquired Dysautonomias

14.2.2.1.3.2.1

#### Equine grass sickness (equine dysautonomia)

Equine dysautonomia has been suggested to be caused by ingestion of botulinum toxin–contaminated feeds principally affecting postganglionic sympathetic and parasympathetic neurons. Brain stem cranial nerve nuclei have neuronal chromatolysis followed by degeneration and loss of lower motor neurons of the general visceral efferent nuclei of cranial nerves III and X and the

## Pathologic Basis of Veterinary Disease, 4th Edition

general somatic efferent nuclei of cranial nerves III, V, VII, and XII. It has been suggested that equine dysautonomia should be classified as a multisystem disease. Clinically, injury of neurons results in dysphagia and gut stasis (colic).

**Fig. 14-115 Dysautonomia, submucosal (Auerbach's) plexus, dog.**

Neuronal central chromatolysis, nuclear pyknosis, and loss of neurons are the characteristic histologic features of enteric dysautonomia reported in dogs, cats, a llama, and horses. (Courtesy Drs. J.F. Zachary and K. Bailey, College of Veterinary Medicine, University of Illinois.)

Although the cause is unknown, oxidative stress, excitotoxicity, fungal toxins, and changes in weather have been proposed. Pasture grasses stressed by rapid growth or sudden cold weather can have reduced concentrations of antioxidants and increased concentrations of glutamate and aspartate (excitotoxic amino acids) and the neurotoxin malonate. It has been proposed that ingestion of high concentrations of these compounds either directly (excitotoxicity-apoptotic cell death) or indirectly (nitric oxide toxicity) induces neuronal injury within the ANS, resulting in alimentary system dysfunction. Because mycotoxins were suspected as a cause of equine grass sickness, studies conducted to investigate this hypothesis demonstrated six species of fungi in pastures from confirmed cases of grass sickness. The significance of these fungi in the pathogenesis of grass sickness is unclear. The similarity between neural lesions induced by *Clostridium botulinum* group III toxins and those in equine dysautonomia has been noted, but the role of such toxins in the disease remains unproven. A recent case report suggests that equine dysautonomia is caused by ingesting grass blades contaminated with botulinum neurotoxin; thus clinically, equine grass sickness has been referred to as a form of botulism.

958

There are no gross lesions in the PNS, except potentially for lesions related to paralytic ileus; however, microscopically and principally in the small intestine (ileum), the cell bodies of neurons in ganglia of the autonomic and enteric divisions of the PNS are chromatolytic, have displaced and pyknotic of nuclei, are swollen and vacuolated, and with time there is neuronal loss and satellite cell proliferation in affected ganglia. Equine dysautonomia affects horses, ponies, and donkeys primarily between the ages of 2 and 7 years old. The disorder occurs principally between the months of April and July. Injury to enteric neurons results clinically in acute to chronic dysphagia and gut stasis (colic). The only way to diagnose equine grass sickness antemortem is by taking a biopsy of the small intestine during surgery.

## 14.2.2.1.3.2.2

### Peritonitis-induced dysautonomias

Degeneration of autonomic neurons in the myenteric and submucosal ganglion (plexuses) can occur in animals with peritonitis. The degree of neuronal degeneration appears to be related to the severity and type of inflammatory response in the peritoneal cavity and the ability of inflammatory mediators and other potentially toxic molecules to reach the ganglia by diffusion or hematogenously. Degeneration does not appear to progress to neuronal cell death if the peritonitis is resolved. Affected neurons have vesicular nuclei that are 2 to 3 times normal size (Fig. 14-115). Nissl substance is also displaced (central chromatolysis). Nerve fiber bundles are edematous, and supporting cells can be remarkably hyperplastic and compress adjacent supporting stroma.

This lesion is thought to arise from inflammatory cytokine-mediated injury to autonomic neurons, and this may cause alterations of intestinal motility. It appears that the morphologic changes observed in autonomic and enteric neuron cell bodies are reversible with resolution of the peritonitis. Whether the neuronal lesion results from diffusion, hematogenous, or retrograde axonal transport of cytokines to the ganglion from the site of inflammation remains to be proven.

This lesion is likely the cause of paralytic ileus seen with peritonitis.

## 14.2.2.1.4

### ENDOCRINE DISEASES

Of the endocrine disorders, hypothyroidism, hyperadrenocorticism, and diabetes mellitus can affect the PNS. The lesions of these neuropathies are not well characterized and can include evidence of primary demyelination, remyelination, and axonal degeneration. Distal portions of the axon are commonly affected. The extent to which demyelination or axonal degeneration is the primary lesion remains to be determined. From a clinical standpoint, it may be difficult to distinguish neurologic signs from those signs attributed to hormonal-influenced injury of myofibers. Clinical signs can be caused by sensory and motor deficits.

## 14.2.2.1.5

### NUTRITIONAL DISEASES

## 14.2.2.1.5.1

### Vitamin A, Vitamin D, and Riboflavin Deficiencies

Nutritional axonopathies are relatively uncommon and are chiefly caused by vitamin A and some of the B vitamin deficiencies. Vitamin A deficiency results indirectly in peripheral neuropathy by affecting bone growth and remodeling. In neonatal calves, the neuropathy is due to narrowing of the optic foramina caused by continued bone deposition with decreased resorption resulting in compression of

## Pathologic Basis of Veterinary Disease, 4th Edition

---

the optic nerves, Wallerian degeneration, and blindness. B vitamin deficiencies are primarily diseases of pigs and poultry. In pigs, deficiency of pantothenic acid (B-complex vitamin, vitamin B<sub>5</sub>) causes a sensory neuropathy with axonal degeneration, demyelination, and chromatolysis and neuron loss in the dorsal root ganglia, resulting in proprioceptive deficits, goose stepping, and dysmetria. The exact sequence of events in pantothenic acid–deficiency neuropathy is controversial because one study in pigs described initial lesions in the axon; whereas a second study described initial lesions in the cell body. Riboflavin deficiency in poultry, named curly toe paralysis, is primarily a demyelinating neuropathy. Peripheral nerves are swollen because of endoneurial edema, and there is subsequent demyelination with mild axonal degeneration.

14.2.2.1.5.2

### Vitamin E Deficiency

14.2.2.1.5.2.1

#### Equine motor neuron disease

Equine motor neuron disease (EMND) resembles amyotrophic lateral sclerosis (ALS) in human beings. Because vitamin E concentrations are very low in affected horses, this and other dietary antioxidant deficiencies have been suggested as a possible factor in the mechanism of equine motor neuron disease. Thus dietary factors, especially the long-term absence (>1 year) of green feeds with high vitamin E concentrations, have been implicated in the pathogenesis of the disease. Vitamin E supplementation may be useful in treating this disease if detected and treated early in its course.

Neural injury in EMND involves the cell bodies and axons of lower motor neurons (ventral horn cells, cranial nerves). Microscopically, cell bodies are swollen, have chromatolysis, and contain spheroids. As the disease progresses, the cell bodies become shrunken and degenerate and are removed by neuronophagia. When the cell bodies are lost, the resulting empty neuronal space can be replaced by astrogliosis. The axons of affected lower motor neurons have lesions consistent with Wallerian degeneration.

959

The injury in lower motor neurons has been attributed to an oxidative stress mechanism because vitamin E is an antioxidant that offsets the harmful effects of free radicals and reactive oxygen species that can cause membrane lipid peroxidation. However, it is not linked to a mutation in the equine Cu/Zn superoxide dismutase gene. This gene regulates the production of the enzyme superoxide dismutase whose function is to convert free radicals and reactive oxygen species (highly toxic to cells) to hydrogen peroxide (much less toxic to cells). The enzyme catalase is used to convert hydrogen peroxide to water and oxygen molecules. The muscle lesion in EMND is atrophy of type I myofibers secondary to loss of type 1 lower motor neurons.

960

Clinically, EMND is characterized by progressive degeneration and loss of lower motor neurons resulting in muscle atrophy, weight loss, difficulty standing, and muscle fasciculation.

14.2.2.1.6

### TOXIC DISEASES

14.2.2.1.6.1

#### Chemicals

These diseases are discussed in greater detail in the CNS. Examples of chemical toxins causing distal axonal degeneration are the vinca alkaloids, vincristine and colchicine, both causing disassembly of microtubules and inhibiting axoplasmic flow. Of interest, taxol—an alkaloid from the western yew

## Pathologic Basis of Veterinary Disease, 4th Edition

---

(*Taxus brevifolia*)—promotes the assembly of and stabilizes microtubules but also causes an axonopathy. An outbreak of distal polyneuropathy has been reported in cats fed commercial diets contaminated with the ionophore salinomycin, used as a coccidiostatic drug in poultry and growth promoter in cows. There was acute onset of lameness and paralysis affecting the hindlimbs that progressed to the forelimbs. Demyelination of peripheral nerves followed the axonal degeneration. Some toxins seem to cause different patterns of injury in the CNS and PNS. For instance, in the CNS, lead is noted to cause neuronal necrosis, whereas in the PNS, demyelination, preferentially affecting Schwann cells, is prominent in some species.

14.2.2.1.6.2

### Other Toxic Neuropathies

A number of toxins can affect the PNS, with or without damage in the CNS. The initial toxic effects can be at the level of the neuron cell body, the axon, or the myelin sheaths. Examples of toxins targeting neuronal cell bodies are organomercurial compounds such as methylmercury and the cancer chemotherapeutic agent doxorubicin. Methylmercury is particularly toxic because it directly alters biochemical reactions. Although methylmercury poisoning can result from ingestion of water or forage contaminated with industrial discharge, in animals the consumption of fish containing excessive concentrations of methylmercury is the most likely source of the toxin. Fish accumulate methylmercury in their muscle as a result of a “normal” environmental process called biomethylation. Biomethylation converts elemental mercury to methylmercury, which is ingested in the diet of fish. In mercury poisoning, sensory neuron cell bodies of the dorsal root ganglion are preferentially involved and the motor neurons are spared; whereas with doxorubicin, both dorsal root ganglion and autonomic cell bodies are affected. Experimental studies suggest that neuronal cell death is caused by apoptosis of neuronal cell bodies resulting in axonal and Wallerian degeneration.

14.2.2.2

### NEUROMUSCULAR JUNCTION DISEASES

14.2.2.2.1

#### MYASTHENIA GRAVIS

Myasthenia gravis is a disorder of neuromuscular impulse transmission at myoneural junctions and results in flaccid paralysis of skeletal muscle. The disease can be caused by an autoimmune mechanism (acquired) or result from inherited genetic abnormalities (congenital). In autoimmune myasthenia gravis, the antibody binds to acetylcholine receptors (type II hypersensitivity) on postsynaptic muscle membranes. This interaction results in distortion of receptors and blocks binding of the receptors with acetylcholine. Acquired myasthenia gravis often occurs concurrently with thymic abnormalities, such as thymoma and thymic hyperplasia. Because the thymus is responsible for immunologic self-tolerance, thymic abnormalities leading to induced alterations in tolerance have been suggested as the mechanism for developing an antibody response against acetylcholine receptors.

Congenital myasthenia gravis is caused by a genetically determined deficiency in the number of acetylcholine receptors expressed in motor end plates.

There are no gross or microscopic lesions in the PNS or CNS caused by myasthenia gravis. Clinical signs and lesions are due to impairment of skeletal and esophageal muscles, and muscle weakness followed by muscle atrophy.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 14.2.2.3 DISEASES CAUSED BY MICROBES

#### 14.2.2.3.1 BACTERIA

##### 14.2.2.3.1.1 Botulism

Botulism is characterized by a flaccid paralysis caused by the neurotoxin of *Clostridium botulinum* type A, B, or C in North America and D in South Africa. The bacterium is a ubiquitous gram-positive spore-forming anaerobe commonly found in soil. This disease most commonly occurs in horses in North America and cows in South Africa. Different forms of botulism affect foals and adult horses. Toxicoinfectious botulism occurs in foals. Foals contract the disease by ingesting soil contaminated with clostridial spores. In past years, spores were thought to vegetate, replicate, and produce toxin in gastric or duodenal ulcers induced by stress or steroids and nonsteroidal antiinflammatory drugs passed in mares' milk. However, recent retrospective studies suggest that gastric or duodenal ulcers are not involved in the pathogenesis of toxicoinfectious botulism in foals. Currently the site of bacterial colonization and toxicoinfection in foals is unknown. In human infants the large intestine is thought to be the site of colonization and toxicoinfection.

960

961

In adult horses, poisoning following ingestion of toxin-contaminated forage and less commonly wound botulism occur. Adult horses contract the disease principally through the ingestion of preformed toxin in contaminated feeds, usually haylage that is prepared and stored improperly. Less commonly, adult horses contract the disease through tissue injury and an anaerobic environment, such as hoof abscesses and skin wounds. Spores of *Clostridium botulinum* are either carried into wounds by nails or other contaminated foreign objects or into gastric ulcers by ingestion of contaminated soil. In either case the spores will germinate only in necrotic tissue that has an anaerobic environment. The bacteria replicate and produce exotoxin, which is absorbed through the capillary endothelium and enters the blood stream. In adult horses that ingest contaminated feeds, the toxin is absorbed from the alimentary system and enters the blood stream.

Other than the wound where the bacteria replicates, the toxin of *Clostridium botulinum* causes no macroscopic and microscopic tissue lesions. Once botulinum toxin is in the blood stream, it enters myoneural junctions and binds to receptors on presynaptic terminals of peripheral cholinergic synapses. The toxin is then internalized into vesicles, translocated to the cytosol, and then mediates the proteolysis of components of the calcium-induced exocytosis apparatus, thus interfering with acetylcholine release. Inhibition (blockage) of the release of acetylcholine results in flaccid paralysis of muscles innervated by cholinergic cranial and spinal nerves, but there is no impairment of adrenergic or sensory nerves.

Clinically, affected horses have progressive paralysis of the muscles of the limbs, mandible, larynx/pharynx, upper eyelid, tongue, and tail. Death is usually caused by flaccid paralysis of the diaphragm resulting in respiratory failure. Blockage of acetylcholine release at presynaptic cholinergic terminals is permanent. Improvement occurs only when axons develop (sprout) new terminals to replace those damaged by botulinum toxin.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 14.2.2.3.2 VIRUSES AND PROTOZOA

Inflammation of the PNS can occur in conjunction with viruses, such as herpesvirus and rabies. Neuritis of the cauda equine in horses and dogs is primarily an inflammatory disorder with secondary demyelination. This neuritis could have an immune-mediated basis, and adenovirus type 1 has been isolated from affected horses, suggesting a previous viral infection. Polyradiculoneuritis and to a lesser extent ganglionitis occur in toxoplasmosis and neosporosis. The vomiting in pigs infected with hemagglutinating encephalomyelitis virus of pigs is presumed to result from altered function of the vagal nucleus and its ganglion and gastric intramural autonomic plexuses.

### 14.2.2.4 LYSOSOMAL STORAGE DISEASES

#### 14.2.2.4.1 GLOBOID CELL LEUKODYSTROPHY

Peripheral nerves are also affected in globoid cell leukodystrophy and lesions are typified by primary demyelination followed by axonal degeneration. Small sensory branches of peripheral nerves are useful sites for biopsies to make the diagnoses (Fig. 14-116). Gross lesions are not evident; however, microscopically, such areas have pronounced loss of myelin and abundant globoid cells (activated blood monocytes).

### 14.2.2.5 TRAUMATIC INJURY

Trauma to peripheral nerves (lower motor or sensory) is relatively common in animals and can result from lacerations, violent stretching and tearing, or compression or contusion. Reaction patterns following PNS injury are analogous to those in the CNS, but peripheral nerves have a greater capacity for repair.<sup>961</sup> Three patterns of lesions in the PNS have been described. Mild injury that leaves the axon intact (neuropraxia) can result in temporary conduction block, but total recovery of function is possible. More severe damage that destroys the axon but leaves the connective tissue framework intact (axonotmesis) results in Wallerian degeneration distal to the point of injury, but the potential for regeneration and reinnervation is good. Finally, severance of the nerve with destruction of the supporting framework (neurotmesis) results in Wallerian degeneration distal to the injury with the potential for regeneration but little chance of normal reinnervation. Destruction of the supporting framework results in fibrosis between the proximal and distal ends of the nerve and this gap may be large depending on the severity of the injury. Fibrous tissue can obstruct the regenerating proximal axon from reaching the distal supporting framework of the axon. If the regenerative response is exuberant but unproductive, a “potentially” palpable bulbouslike growth can form at the severed stump of the proximal axon called a “neuroma.” The pattern of Wallerian degeneration and the reaction of the neuronal cell body to damage of its axon have been described in an earlier section.<sup>962</sup>

**Fig. 14-116 Globoid cell leukodystrophy, small branch of a peripheral sensory nerve, dog.** Primary demyelination, secondary axonal degeneration, and globoid cells (*arrows*) between the nerve fibers. Also see [Figs. 14-92 through 14-94](#). H&E stain. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

14.2.2.5.1

### RECURRENT LARYNGEAL PARALYSIS

Laryngeal paralysis (roarer syndrome) is caused by axonal injury to the left recurrent laryngeal nerve, which results in atrophy of the left dorsal, lateral, and transverse cricoarytenoid muscles and consequently dysfunction of the larynx and laryngeal folds. The cricoarytenoid dorsalis muscle is the main abductor muscle of the larynx, which keeps the arytenoid cartilages in a lateral position. The cause of this axonopathy is unknown, and there may be different causes for different age groups of animals and different forms of the disease. Known causes include: (1) transection of the axon by extension of inflammation from the guttural pouches because the nerve runs through the pouch within a connective tissue fold and (2) other trauma to the nerve. There is also some evidence that laryngeal paralysis may be inherited in younger horses. Currently a genetic age-onset abnormality of axoplasmic flow appears to be the most likely cause in horses in which trauma and inflammation can be excluded as causes.

Affected horses have disabilities of performance and a characteristic and diagnostic “roaring” sound with inspiration. Laryngeal hemiplegia can affect the right or left dorsal cricoarytenoid muscles; however, 95% of cases involve the left side. The cause of this specificity is unclear. Some have suggested it is related to the long course of the left recurrent laryngeal, which extends down into the chest and loops under the arch of the aorta to return to the larynx, but this hypothesis is weakened by the fact that the axonal injury is distal to where the nerve innervates the larynx.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Gross lesions can vary from being recognizable to being inapparent. Microscopically the lesion is Wallerian degeneration. Laryngeal hemiparesis is primarily a disease of large horse breeds between the ages 2 and 7 years old.

14.2.2.5.2

### NEUROGENIC CARDIOMYOPATHY (BRAIN-HEART SYNDROME)

Neurogenic cardiomyopathy is a syndrome in dogs characterized by unexpected death 5 to 10 days after diffuse CNS injury (usually hit by car). Affected dogs die of cardiac arrhythmias caused by myocardial degeneration. Grossly the myocardium has numerous discrete and coalescing pale white streaks and/or poorly defined areas of necrosis. Neurogenic cardiomyopathy is thought to be caused by overstimulation of the heart by autonomic neurotransmitters and systemic catecholamines released at the time of trauma. It is unknown why there is a 5- to 10-day delay in the development of myocardial necrosis.

14.2.2.5.3

### NEUROGENIC SHOCK

Neurogenic shock is caused by an alteration in the function of the ANS and its regulation of muscle tone in systemic blood vascular beds (Fig. 14-117). The onset of neurogenic shock usually coincides with traumatic injury to the CNS; however, the factors that determine whether it occurs are poorly understood. It is thought to be caused by massive discharge of the ANS. Following trauma, there is immediate vasoconstriction of vascular smooth muscle. Vasoconstriction is shortly followed by vasodilatation, expanded circulatory volume, and a reduction in blood pressure leading to shock. Brain-heart syndrome in veterinary medicine is likely a manifestation of neurogenic shock and vasoconstriction of arterioles leading to myocardial necrosis.

14.2.2.6

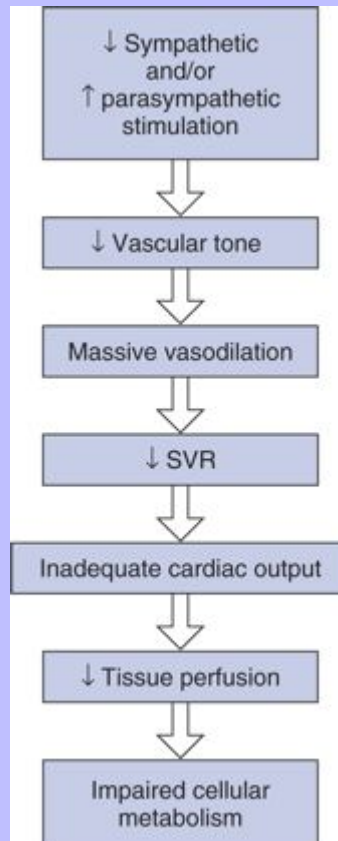

### TUMORS

The objective of this section is to not be all encompassing regarding neoplasms of the peripheral nervous system, but to review one of the best-known examples of how neoplasia can involve this system. Terminology used for neoplasms considered to be of nerve origin in animals is quite confusing. For example, the terms *schwannoma*, *neurofibroma*, and *neurilemmoma* have all been used at various times by different pathologists to identify the same neoplasm. More recently, it has been accepted that the classification of such tumors in veterinary pathology is somewhat arbitrary; therefore these tumors have been simply grouped as benign or malignant peripheral nerve sheath tumors. Malignant tumors show more anaplastic cytoarchitectural features and aggressive growth into adjacent normal tissue. Peripheral nerve sheath tumors occur in both cranial (Fig. 14-118) and spinal nerves (Fig. 14-119) of the PNS. Currently, there are no reliable immunohistochemical markers for these tumors.

962

963

Fig. 14-117 Pathophysiologic mechanism of neurogenic shock. SVR, Systemic vascular resistance. (From Huether SE, McCance KL: Understanding pathophysiology, ed 2, St Louis, 2000, Mosby.)

Schwannomas of animals have been best recognized in the canine and bovine species, and less commonly in the cat. In the dog, the neoplasm most commonly affects the cranial (fifth) or spinal nerve roots (posterior cervical-anterior thoracic roots of the brachial plexus and their extensions and roots at the thoracic and lumbar levels). Although schwannomas of the skin have been reported, there should always be careful consideration of other neoplasms, such as hemangiopericytoma and fibromas, that can have similar morphologic features. The bovine neoplasm occurs most commonly in mature animals, although the lesion has also been reported in young calves and involves the cranial eighth nerve, brachial plexus, and intercostal nerves. Additionally, autonomic nerves of the liver, heart, mediastinum, and thorax can be affected. The skin can be infrequently involved.

Grossly, schwannomas are nodular or varicose thickenings along nerve trunks, or nerve roots. They can be firm or soft (gelatinous) and white or gray. Schwannomas of the spinal cord nerve roots can remain inside the dura mater or extend through the vertebral foramina to the exterior.

**Fig. 14-118 Peripheral nerve sheath tumors.** **A**, Inner surface of the cranial vault, cranial nerves, dog. These tumors are usually lobulated, well-defined, tan, solitary to multiple masses that arise from the coverings of a cranial or spinal nerve (*arrows*). In the central nervous system, the trigeminal nerve is usually affected, and the masseter and temporalis muscles innervated by them may atrophy. Tumors compress the nerves causing Wallerian degeneration. **B**, Brain from dog in [Fig. 14-118, A](#). Peripheral nerve sheath tumors (*arrows*). (*A and B*, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

The main microscopic characteristics described for the human being are also applicable for schwannomas of animals. In human beings, the schwannoma is characterized by having two morphologic features, known as Antoni A and B tissue, and occurs in variable proportions within the neoplasm. Antoni A tissue is cellular and consists of monomorphic spindle-shaped Schwann cells. These cells have poorly defined eosinophilic cytoplasm and pointed basophilic nuclei, and are present in a collagenous stroma of variable extent. The

## Pathologic Basis of Veterinary Disease, 4th Edition

nuclei of these cells are commonly arranged in rows, between which are parallel arrays (stacks) of their cytoplasmic processes, and this arrangement is called a Verocay body. Antoni B areas are also composed of Schwann cells, but their cytoplasm is inconspicuous and their nuclei appear to be suspended in a copious myxoid, often microcystic, matrix. Also, Schwannomas do not typically contain nerve fibers.	963 964
---	------------

**Fig. 14-119 Peripheral nerve sheath tumor, spinal nerve, cow.** These tumors are similar to those described in Fig. 14-118 and occur most commonly in cows and dogs. The terms schwannoma, neurofibroma, and neurilemmoma have been used by different pathologists to identify the same neoplasm. Although schwannoma has been proposed as the best term to classify these tumors, the term *peripheral nerve sheath tumor* groups all morphologic diagnoses under a common umbrella. (Courtesy College of Veterinary Medicine, University of Illinois.)

Schwannomas are differentiated from neurofibromas, which consist of Schwann cells, perineurial cells, and fibroblasts. Some microscopic features of the neurofibroma include elongated spindle cells with poorly defined pale eosinophilic, tapering wavy or buckled nuclei, and numerous small nerve fibers (that are not present in schwannomas). Presence of mast cells is also reported. These neoplastic components are situated

## Pathologic Basis of Veterinary Disease, 4th Edition

in a variably prominent fibromyxoid to myxoid matrix (myxoid neurofibroma), although another variant of the neoplasm contains prominent collagen (collagenous neurofibroma).

### 14.4 Appendix 14-1

964

#### 14.4.1 NECROPSY

965

##### 14.4.1.1 DIFFICULTIES IN THE EXAMINATION OF THE CENTRAL NERVOUS SYSTEM

There are inherent difficulties in performing a satisfactory examination of the central nervous system (CNS) in all animal species, including rapid autolysis and the fact that removal of the brain and spinal cord is very hard work in older, large animals whose bones are very hard. The gross examination of the CNS requires time (30 to 60 minutes) and a reasonable degree of physical strength.

##### 14.4.1.2 NECROPSY PROCEDURES

The brain can be removed from the calvarium without great difficulty, but experience gained in veterinary school (diagnostic necropsy rotations) does make the process more efficient and helps to preserve the anatomic integrity of the brain. In the cow and other mammals with large frontal sinuses (pig), the task is more difficult. The bone of the calvarium is cut and removed using a handsaw, hatchet, or Stryker saw (electrically powered saw) with a large blade in large animals or a small handsaw, Stryker saw with a small blade, bone rongeurs, or bone cutting forceps in smaller animals. The equipment used is dependent on the thickness of the bone and the experience of the prosector.

The head is usually disarticulated from the body at the occipitoatlantal joint before examination. A midline incision should be cut through the skin over the calvarium from the occipito-atlantal joint to a point midway between the eyes. The skin is reflected laterally to expose the entire calvarium and the masseter, temporalis, and other muscles. These muscles should be dissected free from the calvarium. The bone of the calvarium is cut in a plane extending from the foramen magnum to a point just behind the eye on each lateral side of the calvarium. A single cut is then made in the calvarial bone behind the eyes at right angles to the initial two cuts. This approach results in connecting the planes of all these cuts through the foramen magnum. If the cuts are complete and connected, the calvarium can be pulled free from the head by pulling in a rostral to caudal direction. In animals with frontal sinuses, the same process is essentially repeated twice to expose the brain.

Once the calvarium is removed, the dura mater, if not removed with the calvarium, should be cut along the midline and reflected laterally to expose the surface of the brain. The falx cerebri and tentorium cerebelli must be cut and removed before attempting to remove the brain; otherwise the brain can be torn during removal. The head is turned upside down and, at the foramen magnum, the cranial nerve roots severed in descending numerical order to release the brain from the cranial vault. The force of gravity will pull the brain out of the cavity onto the necropsy table.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The spinal cord can be removed from small and large animals, but the process is labor intensive; without experience and proper equipment, the process is prone to spinal cord damage and risk to the prosector. The vertebral column must be separated from the limbs, ribs, and visceral and thoracic organs. In large animals, the vertebral column is cut transversely into cervical, thoracic, and lumbar segments. Each segment is then cut in a lateral to medial direction on a sagittal plane to the depth of the spinal cord on a heavy-duty band saw. When the vertebral canal is reached, the dura mater is longitudinally cut the length of the cord, the spinal nerves are severed, and the spinal cord removed. A similar method can be used in large dogs, but in smaller animals a complete dorsal laminectomy can be performed, and then the above procedure is followed. The anatomic orientation of the spinal cord needs to be maintained for subsequent histopathologic evaluation.

Even light compression of the spinal cord during necropsy will fracture the gray matter. Heavier pressure will squeeze it out like toothpaste. The CNS is very delicate and must be handled carefully. Bone dust from saws can cause confusion in interpretation of the histological sections.

### 14.4.1.3 GROSS EXAMINATION BEFORE FIXATION

Once the CNS has been removed from the calvarium and vertebral canal, and before placing the brain and spinal cord in a fixative, they should be carefully examined for any gross abnormalities. The CNS is a symmetric organ with the right and left sides mirroring each other in structural and functional features across an imaginary midline. These sides should be compared for any alterations in size, symmetry, or color. The sulci, gyri, and the meninges should be examined for inflammation and for any changes suggestive of edema. It is not advisable to section an unfixed specimen of brain or spinal cord unless absolutely necessary.

It is also at this time that a decision must be made regarding the saving of specimens for ancillary testing, such as for bacteriology, virology, and toxicology. The necessity for these tests will be based on the history, findings of the postmortem examination, and probability of a specific disease occurring in the animal. Fresh CNS tissue should be provided for these ancillary tests in quantities sufficient and satisfactory for the requested analysis, but not in a manner that interferes with further macroscopic and microscopic evaluation of the CNS after fixation. Contact your regional diagnostic laboratory for specific information regarding proper sample selection for these ancillary tests and for evaluation of tissues for rabies virus.

### 14.4.1.4 FIXATION PROCEDURES

The CNS should be fixed by immersion in 10% neutral-buffered formalin for histopathologic evaluation. Once the CNS is fixed, it should be sliced like a “loaf of bread” from the olfactory bulbs to the cauda equina in approximately 1-cm-thick sections. The cut surfaces of each section should be carefully examined for changes in size, shape, color, and symmetry when compared with the opposite side. Specimens for microscopic evaluation should be taken from any areas that have visible changes and from areas of the CNS that likely would have lesions for diseases listed in the list of differential diagnoses. In addition, all routine microscopic evaluations of the CNS, in which gross lesions are or are not detected should include specimens from the cerebral cortices (two areas), thalamus/hypothalamus, hippocampus, cerebellum and roof nuclei, brain stem (two areas), and the cervicothoracic and thoracolumbar enlargements of the spinal cord.

The spinal cord and peripheral nerve can be fixed by immersion in formalin. Fetal and neonatal brains should be fixed in 20% neutral-buffered formalin. It is best to fix the entire brain without prior sectioning by submerging it in 10% neutral-buffered formalin and then adding 37% formalin until the brain floats in the

## Pathologic Basis of Veterinary Disease, 4th Edition

---

solution. The brain should not be randomly sliced in the hope of better tissue fixation. These procedures may vary based on the academic institution.

### 14.4.1.5 DISEASES CAUSED BY MICROBES

#### 14.4.1.5.1 VIRUSES

##### 14.4.1.5.1.1 BORNA DISEASE

Borna disease is an encephalomyelitis caused by an unusual enveloped RNA virus that replicates in the nucleus of neurons, has no cytopathic effect, and until 1997 its virions had not been visualized ultrastructurally. The disease has been recognized in Central Europe for more than 250 years. Borna disease virus has been classified as the prototype of a new virus family, Bornaviridae.

Experimental evidence indicates that infection of the CNS via olfactory nerves can follow intranasal viral exposure. The virus is highly neurotropic, similar to rabies virus, and is transported by retrograde axonal transport from the periphery to the CNS. Infection of astrocytes, oligodendroglia, ependyma, choroid plexus epithelial cells, and Schwann cells occurs by direct extension when these cells are in close proximity to virus-infected neurons. The virus can also infect the retina by retrograde axonal transport via the optic nerve and cause blindness under experimental conditions. After reaching the CNS, the virus spreads intraaxonally and transsynaptically (proposed) as described for rabies virus. The virus can then also spread centrifugally via the peripheral nervous system (PNS), resulting in infection of various nonneural tissues, including the lacrimal and salivary glands, endocrine tissues, such as the pituitary and adrenal glands, and other tissues. It has also been determined that peripheral blood monocytes can be infected. Experimentally the specific lesions that develop in the CNS appear to depend on a viral-induced, cell-mediated immune mechanism. Antibody to Borna disease virus does not appear to play any significant role in the disease process.

There are no major gross lesions in the CNS. Microscopic lesions, which are limited to the nervous system, consist of a nonsuppurative encephalomyelitis with neuronal degeneration. Lesions are confined largely to the gray matter and are most severe in the midbrain, midbrain-diencephalon junction, hypothalamus, and hippocampus. Inflammation of the meninges and spinal cord is generally mild. Small, round to oval, eosinophilic intranuclear inclusions occur in neurons of the brain stem, hippocampus, and cerebrospinal ganglia. In the PNS, inflammation occurs in the cranial, spinal, and autonomic ganglia and in the peripheral nerves.

The natural infection, which tends to occur more frequently in the spring and summer, has a broad host range, having been reported in horses and sheep (the most frequently cited species), but also in cattle, goats, domestic cats (staggering disease in Sweden and Austria), dogs, rodents, rabbits, deer, alpacas, llamas, pygmy hippopotami, sloths, ostriches, nonhuman primates, and human beings. Borna disease virus infection in horses was originally considered to result in a high mortality, up to 80% to 100% following 1 to 3 weeks of clinical illness. More recent evidence indicates that the majority of infected animals are either asymptomatic or have mild clinical disease that can be accompanied by behavioral changes, followed by recovery. The clinically severe disease in the horse is still largely confined to certain regions in Germany and Switzerland; the asymptomatic infection, which probably also occurs in other species including human beings, is considered to have a worldwide distribution. Proposed peripheral spread of virus by axonal transport in the autonomic and enteric divisions of the PNS has led

966

967

## Pathologic Basis of Veterinary Disease, 4th Edition

---

to the suggestion that infection of these neurons might cause lesions responsible for colic and other gastroenteric dysfunctions in horses.

Borna disease might also be the first infectious agent recognized to be causally significant in human biologic psychiatry. It is known that behavioral alterations can accompany Borna disease infection in animals (e.g., horses, sheep, domestic cats, and nonhuman primates), especially during the early stages, and also in human beings (schizophrenia, unipolar, and bipolar psychiatric disorders particularly). A proposed mechanism for behavioral alterations involves viral protein interference with neurotransmitter function of infected neurons, particularly those located in the limbic lobe of the brain.

14.4.1.5.1.2

### CLASSICAL SWINE FEVER

Classical swine fever (hog cholera) of pigs is caused by a pestivirus. It has a worldwide distribution, except for several countries, including the United States, from which it has been successfully eradicated. Infection under natural conditions occurs by the oronasal route. The virus initially infects epithelial cells of the tonsillar crypts and surrounding lymphoid tissue and then spreads to submandibular and pharyngeal lymph nodes where it replicates. The virus disseminates via leukocytic trafficking to the spleen, bone marrow, visceral lymph nodes, and lymphoid tissue of the intestine where high titers of virus are attained. Target cells for virus replication include endothelial cells, lymphoid cells and macrophages, and epithelial cells. Hematogenous spread of the virus via leukocytic trafficking to endothelial cells throughout the infected pig is usually completed in 5 to 6 days. Infected animals die of disseminated intravascular coagulation.

Lesions of the acute disease, which primarily result from a tropism of the virus for vascular endothelium with subsequent hemorrhage, are present in many organs, including the kidneys, intestinal serosa, lymph nodes, spleen, liver, bone marrow, lungs, skin, heart, stomach, gallbladder, and CNS. Grossly, cerebral edema may be observed. Microscopic lesions of the CNS occur in both gray and white matter and tend to be most prominent in the medulla oblongata, pons, colliculi, and thalamus, but also occur in the cerebrum, cerebellum, and spinal cord. Lesions are characterized by swelling, proliferation, and necrosis of endothelium; perivascular lymphocytic cuffing; hemorrhage and thrombosis; microgliosis; and neuronal degeneration. Choroiditis and leptomeningitis also occur. Special histochemical stains may be required to satisfactorily identify elementary bodies in mononuclear inflammatory cells. Clinical signs resulting from involvement of the CNS include ataxia, paresis, and convulsions.

14.4.1.5.1.3

### ENTEROVIRUS-INDUCED PORCINE POLIOENCEPHALOMYELITIS

Teschen disease and Talfan disease, the enterovirus encephalomyelitides of pigs, are caused by porcine enteroviruses (family Picornaviridae) are characterized by polioencephalomyelitis. Teschen disease is caused by porcine enterovirus, possibly by serotypes 2 and 3. Natural infection occurs by the oral route and is followed by viral localization and replication in the tonsil, Peyer's patches, and the intestinal tract (primarily ileum, large intestine, and cervical and mesenteric lymph nodes). These viruses then enter the blood stream and spread hematogenously through the blood-brain barrier to the CNS, where they target motor neurons.

No gross lesions are detectable. Cerebral, cerebellar, and spinal cord involvement vary with the different viruses causing the polioencephalomyelitis. All forms of the disease are characterized microscopically by a nonsuppurative polioencephalomyelitis, which targets motor neurons of the

## Pathologic Basis of Veterinary Disease, 4th Edition

---

ventral gray horns and craniospinal ganglia. These viruses cause degeneration of neurons with acute swelling, central chromatolysis, necrosis, neuronophagia, microgliosis, and axonal degeneration. Neuronal necrosis is accompanied by lymphocytic perivascular cuffs, especially in the spinal cord. Astrocytosis, and particularly astrogliosis, also occur. Ganglioneuritis, particularly of dorsal root ganglia of the spinal cord, and variable leptomeningitis of varying severity also occur.

Clinical signs include ataxia, excessive squealing, altered or lost vocalization, irritability, muscular tremors/rigidity, grinding of the teeth, and convulsions. In the different diseases, severity varies from notable and associated with death of affected animals (Tesch disease occurring sporadically in Europe and Africa) to less severe disease with signs that include fever, diarrhea, and paralysis, sometimes most severe in the hind legs, in pigs in North America and some other regions of the world.

14.4.1.5.1.4

### HEMAGGLUTININATING ENCEPHALOMYELITIS VIRAL INFECTION OF PIGS

In 1958 a disease of nursing pigs characterized by high morbidity, vomiting, anorexia, constipation, and severe progressive emaciation was reported in Ontario, Canada. The causal agent was found to be a coronavirus. Infection by the oronasal route, which has been demonstrated experimentally, is followed by viral replication in epithelial cells of the nasal mucosa, tonsils, lungs, and small intestine. After local replication, the virus spreads to the CNS by retrograde axonal transport in the peripheral nerves, which include the trigeminal and olfactory nerves, vagus, and extensions from intestinal plexuses to the spinal cord. Neurons of craniospinal ganglia also are infected. The vomiting associated with the disease is presumed to result from altered function of neurons (in the vagal nucleus and its ganglion, and gastric intramural plexuses in the enteric division of the PNS) secondary to viral infection.

967

968

Gross lesions of the CNS are not present. Microscopic lesions occur in the respiratory tract, stomach, and central and peripheral nervous systems. Similar to enterovirus encephalomyelitis, lesions in the CNS are most pronounced in the gray matter and are characterized by a nonsuppurative meningoencephalomyelitis with neuronal degeneration, lymphocytic perivascular cuffs, and microglial nodules. The caudal brain stem, particularly the medulla and pons, and spinal cord are affected. In the peripheral ganglia, the lesions are nonsuppurative inflammation and neuronal degeneration.

Clinically affected animals may show vomiting caused by neuronal lesions in enteric plexuses, depression, hyperaesthesia, trembling, ataxia, convulsions and paddling of the limbs if laterally recumbent.

14.4.1.5.1.5

### JAPANESE ENCEPHALITIS

Japanese encephalitis is a particularly important disease in human beings, but infection also occurs in horses, pigs, cattle, and sheep. The causative virus is classified as a member of the family Flaviviridae (closely related to St. Louis encephalitis and West Nile virus) and is transmitted by mosquitoes, mainly *Culex tritaeniorhynchus*. In nature, infection is maintained in a cycle involving vector mosquitoes, birds, and pigs. Although young susceptible pigs can have signs, detectable illness is not a feature of viral infection in adult or pregnant pigs. However, transplacental fetal infection during pregnancy can result in mummification and stillbirth of fetuses, or the birth of weak live pigs with nervous signs accompanied by nonsuppurative encephalitis and neuronal degeneration.

Factors involved in the pathogenesis of this viral infection include the recent finding that in rats the ability of the virus to infect neurons is closely associated with neuronal immaturity. Such an

## Pathologic Basis of Veterinary Disease, 4th Edition

age-dependent susceptibility of brain to viral infection has also been noted with other flaviviruses, including St. Louis encephalitis virus and yellow fever virus. The fact that fetal and neonatal pigs and young horses appear to be more susceptible than adult animals suggests that such a correlation could also exist in naturally occurring infections of animals.

Grossly, CNS lesions include mild leptomeningeal congestion and hyperemia and occasional hemorrhages within the brain and spinal cord. Microscopically, neurons in the CNS are the target cell. Lesions are characterized by an early leptomeningitis and encephalitis in which neutrophils predominate followed by nonsuppurative encephalomyelitis. This virus also causes degeneration of neurons, especially Purkinje cells of the cerebellum, with necrosis, neuronophagia, microgliosis, and axonal degeneration. Neuronal necrosis is accompanied by lymphocytic perivascular cuffs. There are no inclusion bodies. The lesions are distributed diffusely throughout the nervous system, but affect the gray matter more than the white matter. Well-documented outbreaks of meningoencephalomyelitis caused by Japanese encephalitis virus in horses have been reported. Young or immature horses are more susceptible to infection than older animals. Its geographic distribution includes India, China, and southeastern Asia.

14.4.1.5.1.6

### LOUPING ILL

Louping ill, a tick-transmitted sheep encephalomyelitis, has been recognized in the British Isles for at least 200 years. It is primarily a disease of sheep but also affects cattle, horses, pigs, goats, red deer, dogs, human beings, and the red grouse. It is caused by a flavivirus (family Flaviviridae) and occurs in the British Isles and Norway. A similar disease of sheep occurs in Turkey, Greece, Bulgaria, and Spain. Some cases have been determined to be caused by similar flaviviruses but are distinct from each other and from louping ill virus. The disease occurs in the spring and summer when ticks are alive.

Following infection caused by the tick *Ixodes ricinus*, the virus replicates in lymph nodes and spleen and reenters the blood stream to cause a high-titered viremia, which is the probable route of infection of neurons. Excretion of the virus in milk of infected ewes and goats has also been reported, with the suggestion that transmission by ingestion is of possible significance in suckling kids.

No major gross lesions are present. Microscopic lesions are characterized by a meningoencephalomyelitis, which is primarily nonsuppurative, although occasional neutrophils can be present. Specific changes also include neuronal degeneration, necrosis, and neuronophagia, most consistently occurring in Purkinje cells of the cerebellar cortex but also affecting neurons of the medulla oblongata, pons, and spinal cord. Lesions in Purkinje cells have been proposed to be at least partially responsible for the unique clinical signs of a peculiar leaping gait displayed by affected animals. No inflammation of spinal ganglia occurs, but inflammation has been detected in sciatic nerves.

14.4.1.5.2

### CHLAMYDIA-INDUCED VASCULOPATHIES

14.4.1.5.2.1

### SPORADIC BOVINE ENCEPHALOMYELITIS

Sporadic bovine encephalomyelitis (chlamydial encephalomyelitis) is uncommon and is caused by *Chlamydophila psittaci* (formally named *Chlamydia psittaci*). The disease was first described in the United States, but cases have since occurred in other countries. Chlamydiae are obligate intracellular organisms now classified as bacteria. *Chlamydophila psittaci* is inhaled or ingested via an oronasal

968

969

## Pathologic Basis of Veterinary Disease, 4th Edition

---

route and infects epithelial cells of oronasal mucous membranes and lungs, endothelial cells, and monocytes and lymphocytes. It appears to spread systemically to infect endothelial cells within the CNS via leukocytic trafficking in monocytes and lymphocytes. Lesions are nonsuppurative meningoencephalomyelitis and serofibrinous polyserositis, arthritis, and tenosynovitis. Gross changes in the CNS, when present, are limited to active hyperemia and edema of the leptomeninges. Microscopic lesions extend throughout the neuraxis and consist of leptomeningeal and perivascular infiltrates of lymphocytes, plasma cells, and a few neutrophils. The basilar leptomeninges are most severely affected. Leukocytes extend into the adventitia of blood vessels accompanied by endothelial swelling and necrosis leading to vasculitis, thrombosis, and ischemia. Additional lesions include neuronal degeneration and parenchymal necrosis with microgliosis. Immune-mediated mechanisms have been suggested as the cause of the vasculitis. Calves younger than 6 to 12 months of age are most susceptible. Affected animals initially are ataxic but terminally may become recumbent and opisthotonos develops.

### 14.5 GLOSSARY OF TERMS

**Astrocytosis:**

increased numbers of astrocytes.

**Astrogliosis:**

reactive astrocytic response with increased number (variable), length, and complexity of cell processes. In the CNS, reparative processes following injury, such as inflammation and necrosis, are facilitated by astrogliosis.

**Axonopathy, distal, of the PNS:**

a neuropathy with degeneration of the terminal and preterminal axon of peripheral nerves.

**Axonopathy, distal of the CNS and PNS:**

degeneration of axons involving distal portions of peripheral nerves, and distal portions of long axons in the CNS (spinal cord).

**Axonotmesis:**

axonal injury of a peripheral nerve in which there is degeneration of the part distal to the site of trauma, leaving the supporting framework intact and allowing for improved potential for regeneration and effective reinnervation.

**Blood-brain barrier of the CNS:**

a barrier to free movement of certain substances from cerebral capillaries into CNS tissue. Relies on tight junctions between capillary endothelial cells and selective transport systems in these cells. Endothelial cell basement membrane and foot processes of astrocytes abutting the basement membrane may play role in barrier function.

**Blood-CSF barrier of the CNS:**

## Pathologic Basis of Veterinary Disease, 4th Edition

---

a barrier that consists of tight junctions located between epithelial cells of the choroid plexus and the cells of the arachnoid membrane that respectively separate fenestrated blood vessels of the choroid plexus stroma and dura mater from the CSF.

### **Blood-nerve barrier:**

a barrier to free movement of certain substances from the blood to the endoneurium of peripheral nerves. Barrier properties are conferred by tight junctions between capillary endothelial cells of the endoneurium and between perineurial cells and selective transport systems in the endothelial cells.

### **Brain edema:**

increase in tissue water within the brain that results in an increase in brain volume. The fluid may be present in the intracellular or extracellular compartments or both. The term also is used to include the accumulation of plasma, especially in association with severe injury to the vasculature.

### **Brain swelling:**

marked, rapidly developing, sometimes unexplained, increase in cerebral blood volume and brain volume because of relaxation (dilation) of the arterioles that occurs after brain injury.

### **Büngner, cell bands of:**

a column of proliferating Schwann cells that forms within the space previously occupied by an axon following Wallerian degeneration. The proliferating column of cells is surrounded by the persisting basement membrane of the original Schwann cells.

### **Central chromatolysis:**

dissolution of cytoplasmic Nissl substance (arrays of rough endoplasmic reticulum and polysomes) in the central part of the neuronal cell body that results from injury to the neuron (often involving the axon). The cell body is swollen, and the nucleus frequently is displaced peripherally to the cell membrane. These structural changes functionally represent a response to injury that can be found (if the cell survives) by axonal regeneration with protein synthesis to produce components of the axon required for fast and slow axonal transport.

### **Cranium bifidum:**

a dorsal midline cranial defect through which meninges alone or meninges and brain tissue may protrude into a sac (-cele), covered by skin.

### **Demyelination:**

a disease process in which demyelination (destruction of the myelin sheath) is the primary lesion, although some degree of axonal injury may occur. Primary demyelination is caused by injury to myelin sheaths and/or myelinating cells and their cell processes. Secondary demyelination occurs with axonal injury, as in Wallerian degeneration.

### **Dysraphism:**

## Pathologic Basis of Veterinary Disease, 4th Edition

---

dysraphia, which literally means an abnormal seam, refers to a defective closure of the neural tube during development. This defect, which may occur at any point along the neural tube, is exemplified by anencephaly, prosencephalic hypoplasia, cranium bifidum, spina bifida, and myeloschisis.	969
	970

### **Encephalitis:**

inflammation of the brain.

### **Encephalo-:**

a combining form that refers to the brain.

### **Encephalopathy:**

a degenerative disease process of the brain.

### **Ganglionitis:**

Inflammation of peripheral (sensory or autonomic or both) ganglia.

### **Gemistocyte:**

reactive, hypertrophied astrocyte that develops in response to injury of the CNS. The cell body and processes of gemistocytes become visible with conventional staining (e.g., H&E stain). The cell bodies and processes of normal astrocytes are not visible with H&E staining.

### **Gitter cell:**

macrophage that accumulates in areas of necrosis of CNS tissue. The cytoplasm is typically distended, with abundant lipid-containing material derived from the lipid-rich nervous tissue. Gitter cell nuclei are often displaced peripherally to the cell membrane. These cells are often referred to as “foamy” macrophages.

### **Hydranencephaly:**

a large, fluid-filled cavity in the area normally occupied by CNS tissue of the cerebral hemispheres resulting from abnormal development. The nervous tissue may be so reduced in thickness that the meninges form the outer part of a thin-walled sac. The lateral ventricles are variably enlarged because of their expansion into the area normally occupied by tissue.

### **Hydrocephalus:**

accumulation of excess CSF resulting from obstruction within the ventricular system (noncommunicating form) associated with enlargement of any or all of the following: lateral ventricles, third ventricle, mesencephalic aqueduct, and fourth ventricle. Hydrocephalus can also occur with communication of the CSF between the ventricular system and the subarachnoid space (communicating form). Hydrocephalus ex vacuo (compensatory hydrocephalus) is characterized by an expansion of the lateral ventricle (or ventricles) that follows loss of brain tissue.

### **Leuko-:**

## Pathologic Basis of Veterinary Disease, 4th Edition

---

combining form referring to white matter of the brain or spinal cord.

### **Leukoencephalitis:**

inflammation of the white matter of the brain.

### **Macroglia:**

a collective term referring to astrocytes and oligodendrocytes. Has also been variously used to refer solely to astrocytes or to astrocytes, oligodendrocytes, and ependymal cells of the CNS, and Müller cells of the retina.

### **Malacia:**

grossly detectable (macroscopic lesion) softening of CNS tissue, usually the result of necrosis.

### **Meningo-:**

combining form referring to meninges.

### **Meningomyelocele:**

a form of spina bifida in which meninges and spinal cord herniate through a defect in the vertebral column into a sac (-cele) covered by skin.

### **Microglia:**

resident cells of the CNS believed to arise from monocytes that populate the brain during embryonic development.

### **Motor neuron, lower:**

large multipolar neurons in the brain stem and ventral horns of the spinal cord with axons extending into the PNS.

### **Motor neuron, upper:**

motor neurons with axons residing solely in the CNS that control lower motor neurons.

### **Myelitis:**

inflammation of the spinal cord.

### **Myelo-:**

combining form referring to spinal cord.

### **Myelopathy:**

a degenerative disease process of the spinal cord.

# Pathologic Basis of Veterinary Disease, 4th Edition

---

**Myeloschisis:**

similar to spina bifida, except in its severe form is characterized by complete failure of the spinal neural tube to close and, therefore, a lack of development of the entire dorsal vertebral column.

**Neuroglial cells:**

astrocytes, oligodendroglia, ependymal cells, and microglia of the CNS.

**Neuronophagia:**

accumulation of microglial cells around a dead neuron.

**Neuropil:**

the gray matter feltwork that consists of intermingled and interconnected processes of neurons (axons and dendrites) and their synaptic junctions, plus processes of oligodendroglia, astrocytes, and microglia.

**Neuropraxia:**

traumatic injury to a peripheral nerve with temporary conduction block but with no permanent axonal damage.

**Neurotmesis:**

complete transection of a nerve and supporting framework with little potential for normal reinnervation.

**Onion bulb:**

concentric arrays of Schwann cell cytoplasm around an axon signifying multiple episodes of demyelination and remyelination.

**Polio-:**

combining form referring to gray matter of the CNS.

**Polioencephalomalacia:**

softening (usually the result of necrosis) of the gray matter of the brain.

**Polioencephalomyelitis:**

inflammation of the gray matter of the brain and spinal cord.

970

**Poliomyelomalacia:**

softening (usually the result of necrosis) of the gray matter of the spinal cord.

971

**Porencephaly:**

## Pathologic Basis of Veterinary Disease, 4th Edition

---

a cleft or cystic defect in the cerebral hemisphere that communicates with the subarachnoid space and also may communicate with the ventricular system. The defect may contain CSF.

### **Radiculoneuritis (polyradiculoneuritis):**

inflammation of a spinal nerve rootlet (or rootlets).

### **Rarefaction:**

reduction in density of CNS tissue that may result from edema, necrosis, etc. This lesion is usually observed microscopically.

### **Satellitosis:**

an accumulation of oligodendroglia around neuronal cell bodies. Although this feature can be seen in normal brains, some consider that it may also be associated with neuronal injury.

### **Sclerosis:**

literally means induration or hardening and, when used in describing lesions of the CNS, often refers to induration or hardening of the brain or spinal cord resulting from astrogliosis (astrocytic scar formation).

### **Spina bifida:**

a dorsal midline defect involving one to several vertebrae of the spinal column caused by failure of the neural tube to close, permitting exposure of the underlying meninges and spinal cord. The lesion may be associated with herniation of meninges alone or meninges and spinal cord tissue into a sac (-cele) covered by skin, or there may be no herniation (spina bifida occulta).

### **Status spongiosus:**

an encompassing term meaning the presence of small focal, ovoid to round “clear (unstained or poorly stained [H&E stain])” spaces in the CNS. The lesion can result from several different tissue alterations, which include splitting of the myelin sheath, accumulation of extracellular fluid, swelling of cellular (e.g., astrocytic and neuronal) processes, and axonal injury (Wallerian degeneration) when swollen axons are no longer detectable within distended spaces.

### **Syringomyelia:**

a tubular cavitation (syrinx) in the spinal cord that is not lined by ependyma and may extend over several segments.

### **Wallerian degeneration:**

degeneration of the distal component of an injured (compressed or severed) axon. Although the term originally referred to injury of axons in the PNS, current usage also includes the CNS. This process also results in functional and structural alterations in the cell body (central chromatolysis) and proximal internode segment of the axon, and in secondary demyelination.

## 15 Chapter 15 Skeletal Muscle

BETH A. VALENTINE

M. DONALD MCGAVIN

### 15.1 INTRODUCTION

Skeletal muscle has many functions in the body. Some obvious and major functions are maintenance of posture and enabling movement, including locomotion. The rhythmic contraction of the respiratory muscles (the intercostal muscles and the diaphragm) is essential for life. In addition, muscles play a major role in whole body homeostasis and are involved in glucose metabolism and maintenance of body temperature. On a purely esthetic level, muscle contributes to pleasing body contours.

The function of skeletal muscle is intimately related to the function of the peripheral nervous system. The physiologic attributes of a muscle fiber—its rate of contraction and type of metabolism (oxidative, anaerobic, or mixed)—are determined not by the muscle cell itself but by the neuron responsible for its innervation, the ventral horn or the brain stem motor neurons (Fig. 15-1). This fact is significant in evaluating histologic changes in muscle fibers. It is possible to divide changes in muscle fibers into two major classes: neuropathic and myopathic. Neuropathic changes are those that are determined by the effect or the absence of the nerve supply (e.g., atrophy after denervation). The term “myopathy” should be reserved for those muscle diseases in which the primary change takes place in the muscle cell, not in the interstitial tissue and not secondary to effects from the nerve supply. The term “neuromuscular disease” encompasses disorders involving lower motor neurons, peripheral nerves, neuromuscular junctions, and muscles.

**Fig. 15-1 Schematic diagram of motor units of a muscle.** Each motor unit consists of a motor neuron within the central nervous system and all the myofibers (muscle cells) supplied by the neuron and its axon branches. (From Huether SE, McCance KL: *Understanding pathophysiology*, ed 3, St Louis, 2004, Mosby.)

#### 15.1.1 NORMAL SKELETAL MUSCLE

Understanding the normal structure and function of muscle, including gross, histologic, biochemical, physiologic, electrophysiologic, and ultrastructural features, is critical to understanding of muscle disease.

### 15.1.1.1 STRUCTURE OF MYOFIBERS

Structural and physiologic features of skeletal muscle determine much of its response to injury. Although muscle cells are frequently called muscle fibers or myofibers, they are in fact multinucleated cells of considerable length, which in some animals may approach 1 meter. Myonuclei are located peripherally in the cylindrical myofiber (Fig. 15-2) and direct the physiologic processes of the cellular constituents in their area through a process known as nuclear domains. This anatomic arrangement allows segments of the cell to react independently of other portions of the cell. Myonuclei are considered terminally differentiated, with little or no capacity for mitosis and thus for regeneration.

973

974

Associated with myofibers are the satellite cells, also known as resting myoblasts (Fig. 15-3). These cells are distributed along the length of the myofiber, between the plasma membrane (sarcolemma) and the basal lamina. Satellite cells in skeletal muscle are very different from cells of the same name found within the peripheral nervous system. Muscle satellite cells are fully capable of dividing, fusing, and reforming mature myofibers. Thus, under favorable conditions, muscle cells (myofibers) are able to fully restore themselves following damage. It is of interest to note that recent studies have found that pluripotent cells derived from bone marrow can also contribute to skeletal muscle repair, albeit only to a very small degree.

**Fig. 15-2 Skeletal muscle, isolated intact myofiber.** Note the multiple peripherally located nuclei (*arrows*). Phase contrast microscopy. (Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.)

**Fig. 15-3 Skeletal muscle myofibers, transverse section.** Note the satellite cell (resting myoblast) located between the sarcolemma (*arrow*) and the basal lamina (*arrowhead*). TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.)

Each myofiber is surrounded by a basal lamina and outside of this by the endomysium, a thin layer of connective tissue containing capillaries. Myofibers are organized into fascicles surrounded by the perimysium, a slightly more robust layer of connective tissue (Fig. 15-4). Entire muscles are encased in the epimysium, a protective fascia that merges with the muscle tendon. This connective tissue framework is not inert, but in fact forms an integral part of the contractile function of muscle by storing and relaying force generated by myofiber contraction.

Ultrastructural examination reveals that skeletal muscle is a highly and rigidly organized tissue, with what are perhaps the most highly structured cells in the body. Each myofiber is composed of many closely packed myofibrils containing actin and myosin filaments. The striations visible with light microscopy (Fig. 15-5) represent the sarcomeric arrangement of muscle cells, in which actin and myosin filaments attached to transverse Z bands form the framework, and other organelles and intracytoplasmic materials are interspersed within this framework (Fig. 15-6). The endoplasmic reticulum of myofibers is called the sarcoplasmic reticulum and is modified to contain terminal cisternae that sequester the calcium ions necessary to initiate actin and myosin interaction and thus contraction. Sarcolemmal invaginations that traverse the cell, the T (for transverse) tubules, allow for rapid dispersion of a sarcolemmal action potential to all portions of the myofiber. The terminal cisternae of two adjacent sarcomeres and the T tubule form what is called the triad (Fig. 15-6, A).

974

975

Fig. 15-4 **Skeletal muscle, transverse section, normal mammalian muscle.** Each myofiber is surrounded by an endomysium of fine collagenous connective tissue. Myofibers are organized into fascicles, which are surrounded by a slightly thicker perimysium. Frozen section, reticulin stain. (Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.)

Fig. 15-5 **Skeletal muscle, longitudinal section, normal mammalian muscle, cytoarchitectural characteristics.** Note the peripherally located myofiber nuclei and cross striations on the muscle fibers. The cross striations correspond to the A bands (*dark lines*) and I bands (*light lines*) in the transmission electron micrograph of [Fig. 15-6, B](#). Myofibers are surrounded by an extensive capillary network (*arrow*). Formalin fixation, H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Neuromuscular junctions can only be visualized using electron microscopy or other specialized procedures (Fig. 15-7). Neuromuscular junctions occur only in specific zones within the muscle, usually forming an irregular “band” midway between myofiber origin and insertion.

15.1.1.2

### TYPES OF MYOFIBERS

Mammalian muscles are composed of muscle fibers of different contractile properties. A common classification of these fibers is based on three major physiologic features: (1) rates of contraction (fast or slow), (2) rates of fatigue (fast or slow), and (3) types of metabolism (oxidative, glycolytic, or mixed). These physiologic differences form the basis of histochemical methods that demonstrate fiber types. There are several fiber-type classifications. Classification of fibers into type 1, type 2A, and type 2B (Table 15-1) has proven to have practical application in muscle pathology. It is the classification used in this text. Type 1 fibers are rich in mitochondria, rely heavily on oxidative metabolism, and are slow-contracting and slow-fatiguing. Type 2 fibers have fewer mitochondria and are glycolytic, fast-contracting, and more easily fatigable. In most species, type 2 fibers can be subdivided into type 2A and type 2B. Type 2B fibers are the fast-contracting, fast-fatiguing, glycolytic fibers that depend on glycogen for their energy supply. Type 2A fibers are mixed oxidative-glycolytic and therefore, although fast-contracting, are also slow-fatiguing. Thus type 2A fibers are “intermediate” in the concentration of mitochondria, fat, and glycogen between type 1 and type 2B.

Most muscles contain both type 1 and type 2 fibers, and these are conveniently demonstrated by the myosin adenosine triphosphatase (ATPase) reaction (Fig. 15-8, A). Notice that the different fiber types are normally intermingled, forming what is called a mosaic pattern of fiber types. In most mature muscles, the staining pattern of the ATPase reaction reverses when sections are preincubated in an acid rather than an alkaline solution. There are examples of both patterns in the illustrations in this section. Acid preincubation can also be used to distinguish type 2A and type 2B fibers (Fig. 15-8, B). Regenerating fibers, classified as type 2C fibers, stain darkly in both acid and alkaline preparations, which is a distinguishing feature. In most species, oxidative enzyme reactions to demonstrate mitochondria will also demonstrate fiber types to some degree (Fig. 15-9, A).

The percentage of each fiber type varies from muscle to muscle (Fig. 15-10). Type 1 fibers (slow-contracting, slow-fatiguing, oxidative) are plentiful in those muscles in which the main function is slow, prolonged activity, such as those that maintain posture. Type 1 predominant postural muscles are most often located deep in the limb. Within the same muscle, the percentage of type 1 fibers often increases in the deeper portions. Muscles that contract quickly and for short periods of time, such as those designed for sprinting, contain more type 2B fibers. Only rarely are muscles composed of only one fiber type (e.g., the ovine vastus intermedius is type 1). Athletic training causes some type 2B fibers to be converted to 2A. There are also variations within breeds and differences in the same muscle in different species. For example, the dog has no type 2B fibers; all canine fibers have strong oxidative capacity (Fig. 15-9, B).

15.1.1.3

### INNERVATION AND MOTOR UNITS

The axons of the peripheral nerve trunks contain terminal branches that innervate multiple myofibers. The terminal branches form synapses with the myofibers at the neuromuscular junction. The myofibers innervated by a single axon form a motor unit, all fibers of which will contract simultaneously following stimulation. Different muscles have different sized motor units that relate to their function. For example, extraocular muscle function does not call for forceful contraction, but rather for many fine movements to

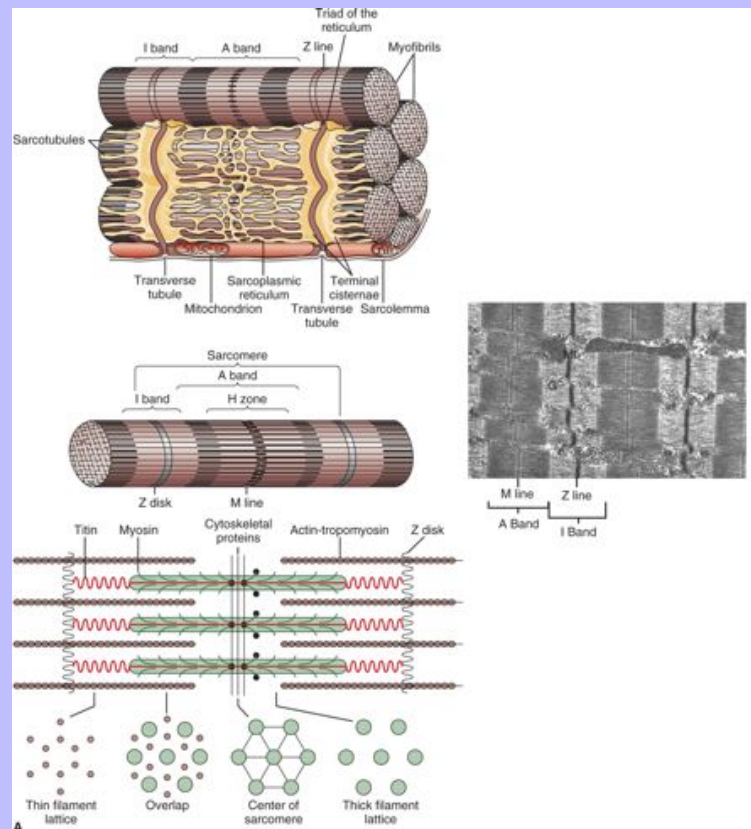

## Pathologic Basis of Veterinary Disease, 4th Edition

smoothly move the globe. Therefore, these muscles have very small motor units, with only a small number of myofibers (1 to 4) innervated by each axon. In contrast, the quadriceps muscle is designed, not for fine movement, but for generation of force, and therefore motor units are quite large, with many myofibers (100 to 150 or more) innervated by a single axon.

975

977

**Fig. 15-6 Myofiber structure.** **A**, Schematic representation of myofiber orientation, secondary organelles, and ultrastructural arrangement of cytoskeletal proteins within sarcomeres. **B**, Skeletal muscle, longitudinal section, normal mammalian skeletal muscle. Sarcomeres are defined by Z lines, A bands composed of thick myosin filaments, and I bands composed of thin actin filaments. Dense M lines with adjacent clear H zones occur in the center of the A band. Mitochondria (Mt) and glycogen (G) are interspersed between the myofibrils. TEM. Uranyl acetate and lead citrate stain. ## Pathologic Basis of Veterinary Disease, 4th Edition

Table 15-1 Skeletal Muscle Fiber Types

Fiber Type	Physiologic Characteristics	Morphologic Characteristics
1	Slow twitch, oxidative, fatigue resistant, "red muscle," aerobic	High mitochondrial content, high fat content, low glycogen content
2A	Fast twitch, oxidative and glycolytic, fatigue resistant	Intermediate mitochondria, fat, and glycogen content
2B	Fast twitch, fatigue sensitive, glycolytic, "white muscle," anaerobic	Low mitochondrial and fat content, high glycogen content

### 15.1.1.4 METABOLISM AND IONIC HOMEOSTASIS

Myofibers require a great deal of energy in the form of adenosine triphosphate (ATP) to generate force and movement. Type 1 oxidative and type 2A oxidative-glycolytic fibers use aerobic metabolism of glucose, stored in the muscle as glycogen, and fat. Type 2B glycolytic fibers rely primarily on anaerobic metabolism of glycogen for energy. Inherent or acquired metabolic defects that reduce skeletal muscle energy production can result in severe muscle dysfunction. A commonly encountered postmortem change, rigor mortis, illustrates the importance of ATP generation within skeletal muscle. The muscle contractile apparatus is still active immediately following death. ATP is necessary for the release of actin from myosin, the interaction that results in the sliding of myofilaments and contraction of muscle. Following death, the absence of adequate ATP production causes the muscle fibers to undergo sustained contraction, known as rigor mortis. Rigor mortis eventually disappears because of muscle structural breakdown due to autolysis or putrefaction (bacterial decomposition). The period of time for onset and release of rigor mortis varies depending on physiologic and environmental factors.

977

978

**Fig. 15-8 Muscle fiber typing, myofibrillar adenosine triphosphatase (ATPase) reaction, normal skeletal muscle, transverse section.**  
**A**, Dog. Type 1 (*light*) and type 2 (*dark*) fibers are arranged in a mosaic pattern. Frozen section, ATPase pH 10.0. **B**, Horse. Acid preincubation allows differentiation of three fiber types, type 1 (*dark*), type 2A (*light*), and type 2B (*intermediate* = *gray*). Frozen section, ATPase 4.35. (**A** and **B**, Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.)

**Fig. 15-9 Mitochondria, NADH reaction (blue stained), skeletal myocytes, normal skeletal muscle, transverse section. A, Horse.** Type 1 fibers contain the most mitochondria, type 2B the least, and mitochondrial content of type 2A fibers is intermediate between type 1 and type 2B. Frozen section, NADH reaction. **B, Dog.** All fiber types have a similar mitochondrial content; therefore this reaction cannot be used to identify different types of myofibers in canine muscle. Frozen section, NADH reaction. (*A and B, Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.*)

Skeletal muscle is also excitable tissue, similar to that of the nervous system. Maintenance of proper ionic gradients across the sarcolemma is essential for initiation of the action potential. Internal ionic gradients, especially of calcium ions, are critical for initiation and termination of contraction. Alterations of ionic

## Pathologic Basis of Veterinary Disease, 4th Edition

fluxes across the sarcolemma, or within the sarcoplasmic reticulum, can have a serious negative impact on myofiber function.

**Fig. 15-10 Schematic diagram of the percentage of type 1 and type 2 myofibers in limb muscles in the dog.** There is a wide variation from muscle to muscle. Deeply located muscles have the most type 1 myofibers, indicative of their function in maintaining posture. (Redrawn from Armstrong RB, Sauber CW, Seeherman HJ, Taylor CR: *Am J Anat* 163:87-98, 1987.)

### 15.1.2 DIAGNOSIS OF MUSCLE DISORDERS

The decision to closely examine muscle, either by a biopsy or at necropsy, relies on recognition of indicators of neuromuscular dysfunction.

#### 15.1.2.1 CLINICAL FINDINGS

Clinical signs of muscular disease are variable (Box 15-1). The most common manifestations are alteration in muscle size, weakness, and abnormal gait. Depending on the nature of the disorder, clinical signs can be localized, multifocal, or generalized.

Alteration in muscle size is readily detected with careful physical examination. Unilateral atrophy is best appreciated by comparing muscles on both sides of the body. In cases of generalized atrophy, it is important to bear in mind the normal muscling of the breed. For example, the muscling of dairy cattle is less prominent than that of beef cattle, and mild generalized muscle atrophy in a draft horse breed will be more difficult to detect than in a light horse breed.

978

979

##### 15.1.2.1.1 Box 15-1 Clinical Signs of Muscle Disease

Muscle atrophy

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Muscle hypertrophy  
Muscle swelling  
Weakness  
Muscle spasm  
Abnormal gait  
Esophageal dysfunction (dogs, camelids)

Weakness can be obvious, as in an animal that is unable to rise or prefers to remain recumbent, or can be manifested primarily as exercise intolerance. Special attention should be paid to gait analysis. The gait of an animal with generalized weakness due to muscle or peripheral nerve dysfunction will have a short stride and often be stiff, and all four legs are often positioned well under the body for support while standing. The abnormal gait of an animal with neuromuscular disease must be distinguished from a similar gait that can occur because of musculoskeletal disease (which is a misnomer, as these disorders affect bone and joint, not muscle). Muscle or peripheral nerve dysfunction in the horse, with this species' unique biomechanics of the pelvic limb, can result in mechanical lameness that can be mistaken for neurologic disease. Odd equine hindlimb gaits designated with such terms as shivers, stringhalt, and fibrotic myopathy are caused by muscle or peripheral nerve disorders. A fibrotic myopathy-like condition also occurs less commonly in the dog and can involve the forelimb. Severe denervating or progressive myopathic conditions that begin in utero or at an early age can cause joint contractures and limb deviation ([Fig. 15-48](#)).

Animals with myotonia often exhibit a stiff gait and develop episodic muscle spasms that can lead to collapse. Percussion of muscle groups can cause a persistent muscle contraction known as “dimpling.”

In dogs, horses, and ruminants, the esophagus contains a large percentage of skeletal muscle. In dogs and camelids, myopathic, neuropathic, and neuromuscular junction disorders can involve these muscles, causing esophageal dysfunction and megaesophagus. Denervation can also contribute to esophageal dysfunction in cattle with vagal indigestion.

As far as can be determined by clinical evaluation and extrapolation from similar conditions in other species, most neuromuscular disorders in animals are not associated with pain. Muscle cramps, due either to primary myopathy or partial denervation, and muscle swelling are exceptions to this rule.

### 15.1.2.2

#### CLINICOPATHOLOGIC FINDINGS

If the plasma membrane of the myofiber is damaged or a segment of the myofiber becomes necrotic, some of the contents of the muscle cell will “leak out” and be taken up into the blood. The concentrations of some of these components in serum are used as an index of the extent of myofiber damage. The most commonly used is creatine kinase (CK), formerly called creatine phosphokinase (CPK). Aspartate aminotransferase (AST), formerly known as serum glutamic-oxaloacetic transaminase (SGOT), and lactic dehydrogenase (LDH) are also released but are not as specific an indicator of muscle damage because they are also present in other tissues. Because CK has a low renal threshold, it is quickly excreted in the urine. The half-life of circulating CK varies somewhat between species but is generally about 6 to 12 hours. The half-life of AST and LDH in the serum is much longer, and serum AST and LDH concentrations remain elevated for several days following muscle injury. Serum concentration of alanine aminotransferase (ALT)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

will also increase in all species from severe muscle cell necrosis. Other serum indicators of skeletal muscle injury include carbonic anhydrase III and fatty acid binding protein, but these latter proteins are not part of a routine serum chemistry panel. It has been speculated that the sarcolemma can become “leaky,” leading to release of CK and other enzymes, without the affected segment becoming overtly necrotic. This possibility is very hard to prove or disprove.

Although the laboratory testing for CK and AST is relatively standardized, laboratory normal ranges may vary considerably. Determining the normal range of blood values for animals is a difficult task. Normal serum CK concentration in animals is generally less than 500 U/L. Normal serum concentrations of AST, ALT, and LDH vary greatly between species. Tests included in chemistry panels also vary. Some laboratories do not include CK in small animal chemistry panels, which can result in a misdiagnosis of hepatic disease in a dog or cat with a persistent increase in serum AST and ALT concentrations because of degenerative muscle disease. For the purposes of discussion in this chapter, a mild increase in CK or AST is considered to be up to 2 to 3 times normal, a moderate increase is 4 to 10 times normal, and a severe increase is 10 times normal or more.

It should be emphasized that myofibers can be dysfunctional without undergoing necrosis. Myopathic and neuropathic conditions resulting in atrophy, weakness, spasm, stiffness, or myotonia rarely result in significant increase in serum muscle enzyme concentrations. At this time there is no biochemical parameter that will assess muscle fiber function; only muscle fiber integrity can be assessed.

979

15.1.2.3

### ELECTROMYOGRAPHY

980

Electromyopathy (EMG) can be a valuable tool when evaluating patients with suspected neuromuscular disease. Concentric needle EMG studies look for abnormal spontaneous activity generated by myofibers. In contrast to other electrodiagnostic studies, a flat line generated by a noncontracting muscle indicates a healthy muscle. Abnormal spontaneous activity includes wave forms designated as positive sharp waves, fibrillations, and myotonic bursts. These abnormal spontaneous electrical events are associated with characteristic sounds emitted by the EMG machine. Abnormal spontaneous activity, typically dense and sustained fibrillations and sharp waves, is generated in denervated muscle because of alteration in sodium channel activity in the membrane of denervated fibers. Spontaneous activity in degenerative myopathies, usually scattered fibrillations, positive sharp waves, and myotonic bursts, is likely related to ionic disturbances associated with fiber degeneration and regeneration; functional denervation following segmental necrosis of the segment containing the neuromuscular junction is also possible. Myotonic conditions result in notably abnormal ionic fluxes leading to waxing and waning of spontaneous potentials with a characteristic “dive bomber” sound. Severe denervating and degenerative disorders, and canine cushingoid myotonia, can be accompanied by myotonic bursts that start and stop abruptly, characteristic of pseudomyotonia.

Nerve conduction velocity studies evaluate the integrity and function of the peripheral nervous system. Primary demyelinating disorders will result in severe reduction of nerve conduction velocity, but axons are intact and muscles are still technically innervated; therefore spontaneous activity does not occur. Repetitive nerve stimulation tests the function of the neuromuscular junctions.

15.1.2.4

### METHODS OF EXAMINATION OF MUSCLE

A variety of examination techniques are often necessary to best appreciate changes occurring in muscle.

### Gross Pathology and Muscle Sampling

Gross examination includes evaluation of changes in size (atrophied, hypertrophied, or normal), color, and texture. The gross pathologic appearance of skeletal muscle can be quite deceiving. What appear to be mild changes in muscle on gross examination often can be severe on microscopic examination, and what appear to be severe changes on gross examination can turn out to be artifact. Subjective evaluation of size can be highly unreliable unless control muscles (e.g., from normal animals or from the opposite sides) are available for weighing and measuring.

Color changes are common. The intensity of the red color of muscle varies depending on the type of muscle, the age and species of animal, and the extent of blood perfusion. Pale muscle can indicate necrosis (Fig. 15-11, A and B; Figs. 15-30, 15-38, A, 15-40, A, and 15-44) or denervation (Fig. 15-11, C; Fig. 15-41), but is also common in young animals and anemic animals. Pale streaking of muscle most often reflects myofiber necrosis and mineralization (Fig. 15-11 A and B) or infiltration by collagen or fat (Fig. 15-11, C and D), and is one of the more reliable indicators of gross pathologic changes. Muscle parasites can be grossly visible as discrete, round to oval, pale and slightly firm zones (Figs. 15-45 and 15-46, A). Dark red mottling of skeletal muscle can indicate congestion, hemorrhage, hemorrhagic necrosis (Figs. 15-36, A and 15-42), inflammation, or myoglobin staining following massive muscle damage (Fig. 15-40, A) or can simply reflect vascular stasis (hypostatic congestion) following death. Hemorrhagic streaks within the diaphragm often accompany death caused by acute exsanguination. A green discoloration can indicate either eosinophilic inflammation (Fig. 15-12) or severe putrefaction. Lipofuscin accumulation in old animals, especially cattle, can cause a tan-brown discoloration of muscle. Black discoloration of the fascia occurs in calves with melanosis as an incidental finding and in older gray horses with metastasis of dermal melanoma to muscle fascia.

Evaluation of texture is also important. Severely thickened and often calcified fascia occurs in cats with fibrodysplasia ossificans progressiva. Fat infiltration or necrosis can result in abnormally soft muscle. Decreased or increased muscle tone can be the result of denervation. Decreased tone can also occur as a result of a lack of muscle conditioning or to postmortem autolysis.

Careful microscopic examination of multiple muscles is often required to detect lesions. In cases of suspected neuromuscular disease, multiple muscle samples should include active muscle (tongue, diaphragm, intercostals, masticatory muscles), proximal muscle (lateral triceps, biceps femoris, semimembranosus, semitendinosus, gluteal), and distal muscle (extensor carpi radialis, cranial tibial). For purposes of a biopsy, certain muscles (e.g., lateral triceps, biceps femoris, cranial tibial, semimembranosus, and semitendinosus) are easier to sample because of their parallel myofiber orientation. The ideal samples will also vary depending on the suspected disorder, such as a type 1 predominant postural muscle for diagnosis of equine motor neuron disease, a type 2 predominant locomotory muscle for diagnosis of equine polysaccharide storage myopathy, and temporal or masseter muscle for diagnosis of masticatory myositis in dogs and masseter myopathy in horses. For physiologic studies in which intact muscle fibers are necessary, and for studies of neuromuscular junction zones, short fibers such as those in the intercostal muscle are preferred.

**Fig. 15-11 Pathologic changes resulting in pale skeletal muscle.** **A**, Pale streaks, necrosis and mineralization, degenerative myopathy, canine X-linked muscular dystrophy, diaphragm (*left side*), dog. **B**, Localized pallor, necrosis, injection site of an irritant substance, semitendinosus muscle, cow. The irritant was injected just under the perimysium and caused necrosis and disruption of the myofibers. Some irritant seeped down between the fascicles to cause necrosis, but the fascicles of myofibers are still in place. **C**, Overall pale muscle with pale streaks from collagen and fat infiltration, denervation atrophy, equine motor neuron disease, horse. Equine motor neuron disease muscle (*right*) compared with normal muscle (*left*). **D**, Enlargement and pallor, steatosis, longissimus muscles, neonatal calf. The majority of the muscles have been replaced by fat. (**A**, Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University. For histopathologic findings, see [Fig. 15-49](#). **B** and **D**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. For histopathologic findings, see [Fig. 15-29](#). **C**, Courtesy Dr. A. de Lahunta, College of Veterinary Medicine, Cornell University. For histopathologic findings, see [Figs. 15-23](#) and [15-41](#).)

To ensure proper fixation and orientation of sections prepared from fixed specimens, the sample should be a strip of muscle no more than 1 cm in diameter, with myofibers running lengthwise. Muscle

## Pathologic Basis of Veterinary Disease, 4th Edition

maintains the ability to contract for some time after death, with the time varying depending on the physiologic state of the muscle at the time of death and on the postmortem interval. Contraction of muscle following contact with fixative is the most common cause of an artifact—called contraction band artifact. Contraction can be prevented or at least minimized by use of a specially designed muscle clamp (Fig. 15-13, A) or by placing the sample on a rigid surface, such as a portion of a tongue depressor, and fixing the ends with sutures, staples, or clamps before submersion in the fixative (Fig. 15-13, B).

### 15.1.2.4.2

#### Microscopic Examination

Frequently, lesions in muscles can be detected and evaluated only by microscopic examination. Proper microscopic examination requires evaluation of both transverse and longitudinal sections. Myofiber diameters, cytoarchitectural changes, and the percentage of abnormal myofibers are most reliably evaluated in transverse sections. Longitudinal sections reveal the length of changes, such as segmental necrosis or regeneration or deposition of storage material. Improperly oriented samples, which result in sections that have obliquely oriented myofibers and thus neither longitudinal or transverse myofibers, are difficult to evaluate. Use of a magnifying glass or dissecting microscope can aid in determining the orientation of myofibers during trimming of muscle before sectioning. Routine stains, such as

981

982

hematoxylin and eosin (H&E), run the risk of offering the pathologist a “vast pink wasteland” for evaluation (Fig. 15-14, A) and are often inadequate for detecting subtle myopathic changes, lesions within intramuscular nerves, or presence of abnormal stored material. Various special stains, including reticulin, Masson trichrome, von Kossa, lipid (performed on frozen sections of fixed samples), and periodic acid–Schiff (PAS) for glycogen, are often invaluable in evaluation of routinely processed skeletal muscle (Table 15-2). Examples of many of these can be found in this section. Other valuable stains and reactions can only be performed on frozen sections of unfixed muscle samples (Table 15-2).

**Fig. 15-12 Bovine eosinophilic myositis, gluteal muscles, cow.** Green discoloration of the muscle is due to inflammation that has abundant eosinophils. The inflammation is attributed to degenerating *Sarcocystis* spp. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. For histopathologic findings, see Fig. 15-43.)

**Fig. 15-13 Techniques for collection of a muscle sample for histologic examination.** **A**, Commercially available clamps are used to prevent contraction of a fresh muscle specimen when immersed in 10% neutral-buffered formalin. **B**, Pinning strips of muscle onto a rigid surface, such as a piece of tongue depressor before immersion in 10% neutral-buffered formalin, will also minimize fixation artifacts but is not as effective as the clamps shown above. (**A**, Courtesy Dr. L. Fuhrer, Clinic Veterinaire de St. Avertin, France. **B**, Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.)

For many decades, myofiber typing could be done only on frozen sections using the myosin ATPase reaction. Recently, immunohistochemical staining of myosin has been developed for demonstration of myofiber types in formalin-fixed muscle. This is a major advantage because fiber-type staining is often essential for the complete evaluation of muscle. It is most useful in demonstrating preferential involvement of a fiber type and alteration of the fiber-type pattern because of denervation and reinnervation.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 15-2 Useful Special Stains and Enzyme Reactions

	Stain	Use
<b>Routine sections</b>	Masson trichrome	Differentiates collagen (blue) from muscle (red); highlight nerves; differentiate myelin (red) from collagen (blue)
	Reticulin	Identifies reticular fibers of the muscle interstitium; outline individual fibers
	PTAH	Stains cross striations in muscle
	von Kossa	Identifies carbonates and phosphates linked with calcium in mineralized fibers
	Alizarin red S	Identifies calcium in necrotic and mineralized fibers
	PAS	Identifies glycogen and proteoglycans; also stains protozoal cysts
<b>Frozen sections</b>	PAS with amylase (diastase)	Differentiates proteoglycans (amylase resistant) from glycogen (amylase sensitive)
	Modified Gomori's trichrome	Identifies mitochondria (red), differentiates myelin (red) from collagen (green) in nerves
	NADH, SDH, cytochrome oxidase	Identifies mitochondrial enzyme activity
	ATPase	Differentiates fiber types
	Acid phosphatase	Detects macrophages and denervated fibers
	Nonspecific esterase	Detects macrophages and denervated fibers; identifies neuromuscular junctions
	Oil red O; Sudan black	Identifies lipid
	von Kossa, alizarin red S, PAS with and without amylase (diastase)	Same as in routine sections

*ATPase*, Adenosine triphosphatase; *NADH*, nicotinamide adenine dinucleotide dehydrogenase; *PAS*, periodic acid-Schiff; *PTAH*, phosphotungstic acid hematoxylin; *SDH*, succinate dehydrogenase.

15.1.2.4.2.1

### Enzyme histochemistry and immunohistochemistry

There is no question that frozen section histochemistry of unfixed muscle samples is the “gold standard” of muscle pathology. Skeletal muscle may be the one tissue in which the morphology of cells and cellular components is best appreciated in frozen sections (Fig. 15-14, B). Routine frozen section histochemistry on muscle includes a battery of stains applied to serial sections. Examples of many of these are provided in this section. Stains applied include H&E, modified Gomori's trichrome, ATPase for fiber typing, nicotinamide adenine dinucleotide dehydrogenase (NADH), succinate dehydrogenase (SDH), cytochrome oxidase, and other mitochondrial enzyme stains, PAS for glycogen, alizarin red S for calcium, alkaline phosphatase and nonspecific esterase for macrophages and denervated fibers, and lipid stains. When indicated, frozen sections also allow for immunostaining for cytoskeletal proteins, such as dystrophin (Fig. 15-50) and the dystrophin-associated proteins. Certain abnormal structures—such as nemaline rods formed by expansion of Z bands, as seen in nemaline rod myopathy—are not visible in routine sections, but are readily identified in frozen sections stained with modified Gomori's trichrome.

The major disadvantage of frozen section histochemistry is that, unless a neuromuscular disease laboratory is readily available to immediately process unfixed muscle samples, careful preparation for overnight shipping, on ice, in a moist but not overly wet environment, is necessary. Any delay in shipment, or overwetting or overheating of the sample, will result in nondiagnostic samples. In addition, preparation of frozen sections is time and labor intensive, and in most cases only a single

## Pathologic Basis of Veterinary Disease, 4th Edition

---

transverse section approximately 1 cm in diameter will be examined. This can create a significant sampling error when evaluating a small sample of a large muscle in which lesions may not be evenly distributed.

Complete evaluation to include morphometric examination and calculation of the percentage and mean diameter of each fiber type will detect changes in the percentage of each fiber type and fiber atrophy or hypertrophy. But at this time, morphometric analysis is not routinely performed on samples submitted for diagnostic purposes.

Frozen section histochemistry will always be a powerful tool for evaluation of muscle disease. But in many disorders, it is possible to obtain diagnostic sections from routinely processed muscle samples when appropriate sample selection, handling, and processing are performed, and sections are examined by a pathologist familiar with muscle pathology.

983

984

### 15.1.2.4.2.2

#### Electron microscopy

Although much of what used to be determined by electron microscopy has been supplanted by newer immunohistochemical procedures, electron microscopic evaluation of muscle is still important. Various structural alterations, such as abnormalities of neuromuscular junctions, mitochondria, sarcomeric disarray, sarcotubular dilation, Z-line streaming, and cytoplasmic inclusions may be best visualized, and in some cases only visualized, by this method. Sampling and handling methods to minimize contraction and other artifacts and to allow for precise transverse and longitudinal sections are imperative.

### 15.1.2.4.3

#### Other Methods of Evaluation

Physiologic testing of isolated intact myofibers in vitro forms the basis for diagnosis of malignant hyperthermia. Short fibers, such as from samples of intercostal muscle, are preferred. While maintained in a physiologic solution, myofiber bundles are exposed to various agents, such as caffeine and halothane, to detect abnormal contractural sensitivity. Biochemical and molecular biologic analysis of muscle samples can evaluate levels of muscle enzymes and other proteins, and genetic analysis can be performed to detect specific gene defects. These latter tests require fresh muscle samples snap-frozen in liquid nitrogen and maintained at  $-70^{\circ}\text{C}$  until analysis.

### 15.1.3

#### PORTALS OF ENTRY

Portals of entry are summarized in [Box 15-2](#). Injury to muscle can occur secondary to trauma or infection. Muscle lying superficially can be damaged by penetrating wounds, including those created by intramuscular injections ([Figs. 15-11, B](#) and [15-15](#)), which can also allow entry of infectious agents. Muscles located deeply are often injured following bone fracture. Crush injuries from external forces will cause extensive muscle damage, and excessive tension can cause muscle tearing. Muscles are endowed with an extensive vascular network that can allow entry of blood-borne pathogens, immune complexes, antibodies and toxins, and inflammatory cells.

Other routes by which muscle can become dysfunctional are summarized in [Box 15-3](#). Some muscular disorders are genetically determined. Inherited or acquired dysfunction of motor neurons or nerves will cause muscle injury in the form of atrophy. Toxins or an altered endocrine or electrolyte status can affect muscle, and physiologic damage can be caused by exhaustive or overexuberant exercise.

### 15.1.4 DEFENSE MECHANISMS

Defense mechanisms are summarized in [Box 15-4](#). The thick encircling fascia (epimysium) of many muscles provides some protection from penetrating injuries and from extension of adjacent infection. This fascia can, however, also contribute to injury under circumstances that lead to increased intramuscular pressure causing hypoxia (compartment syndrome). Tissue macrophages are not typically found in normal muscle, but are recruited rapidly from circulating monocytes in the vasculature. Macrophages can cross even an intact basal lamina and effectively clear debris from damaged portions of myofibers, allowing for rapid restoration of the myocyte through satellite cell activation. Neutrophils and other inflammatory cells are also recruited from the blood stream in response to injury or infection. The extensive vascular network of muscle includes extensive collateral circulatory pathways that render muscle relatively resistant to ischemic damage caused by thrombosis or thromboembolism. Despite the high vascular density of muscle, metastasis of neoplasms to muscle is quite rare. There is some evidence to suggest that the capillary endothelium of skeletal muscle is inherently resistant to neoplastic cell adhesion and invasion.

## 15.1.5 RESPONSE OF MUSCLE TO INJURY

It is often said that the range of response of muscle to injury is limited, consisting primarily of necrosis and regeneration. Actually, muscle is a remarkably adaptive tissue, with a wide range of response to physiologic and pathologic conditions. Myofibers can add or delete sarcomeres to cause elongation or shortening of the entire muscle. In addition to necrosis and regeneration, myofibers can atrophy and hypertrophy, they can split, they can undergo a variety of cytoarchitectural alterations, and they can completely alter their physiologic functions when undergoing fiber-type conversion. To describe muscle response to injury as stereotypical does not do justice to this inherent plasticity. What is true, though, is that it is frequently not possible to determine the cause of muscle injury based on gross or histologic lesions alone. Supplementary tests and clinical histories are often essential.

### 15.1.5.1 NECROSIS AND REGENERATION

Myofiber necrosis can accompany a variety of disorders. Because of their multinucleate nature, myofibers often undergo segmental necrosis, with involvement of only one or several contiguous segments within the cell. More than 100 years ago, Zenker described segmental hyaline degeneration (Zenker's necrosis) in the muscles of human patients dying of typhoid, and this term may still be found in some of the older literature. Global necrosis of the entire length of the myofiber occurs only under severe duress, such as extreme pressure to the entire muscle causing crush injury, or widespread ischemia because of pressure on, or thromboembolism of, a large artery.

Necrotic portions of myofibers have several different histologic appearances. The earliest change is often segmental hypercontraction, resulting in segments of slightly larger diameter that are slightly darker staining ("large dark fibers") that are best seen on transverse sections ([Fig. 15-16, A](#)). On longitudinal sections, "twisting" or "curling" of affected fibers is often seen. But similar changes occur as an artifactual

## Pathologic Basis of Veterinary Disease, 4th Edition

---

change in improperly handled samples. The cytoplasm of fully necrotic portions of the fiber is often homogeneously eosinophilic and pale (hyaline degeneration), with loss of the normal cytoplasmic striations and the adjacent muscle nucleus. The affected cytoplasm then becomes floccular or granular as that portion of the myofiber starts to fragment ([Fig. 15-16, B](#); [Fig. 15-18, B](#)).

Increased intracellular calcium is a common trigger of necrosis in all cells, and myofibers contain a high level of calcium ions stored in the sarcoplasmic reticulum. Therefore myofibers may be particularly sensitive to calcium-induced necrosis either as a result of damage to the sarcolemma, causing influx of extracellular calcium, or from damage to the sarcoplasmic reticulum, releasing intracellular stores of calcium. Small wonder then that necrotic myofibers are often prone to overt mineralization. Overtly mineralized myofibers appear as chalky white streaks on gross examination ([Fig. 15-11, A](#)) and as basophilic granular to crystalline material within myofibers on histologic examination. Large deposits of mineral can induce a foreign body granulomatous response. Although the presence or absence of myofiber mineralization has sometimes been used as a diagnostic aid, the circumstances under which a necrotic myofiber segment can become mineralized are so diverse that myofiber mineralization must be considered a nonspecific response, indicative only of myofiber necrosis. Myofiber mineralization can be confirmed with histochemical stains, such as alizarin red S and von Kossa. Histochemical staining for calcium in frozen sections will also detect increased intracytoplasmic calcium in damaged myofibers that are not overtly necrotic or mineralized ([Fig. 15-17, A](#)).

---

Fig. 15-16 **Myofiber necrosis, skeletal muscle.** **A**, Hypercontraction, transverse section. Frozen section, nonspecific esterase stain. (**A**, Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University. **B**, Courtesy Dr. B.J. Cooper, College of Veterinary Medicine, Oregon State University.)

Provided there is still an adequate blood supply, macrophages derived from transformation of blood monocytes will rapidly infiltrate areas of myofiber necrosis (Fig. 15-17, B). Macrophages are able to traverse the basal lamina and rapidly clear cytoplasmic debris (Fig. 15-18, A). Other leukocytes, including neutrophils, eosinophils, and lymphocytes, can also be recruited to sites of extensive myonecrosis, presumably because of various cytokines released from damaged muscle. The infiltration of macrophages

## Pathologic Basis of Veterinary Disease, 4th Edition

---

and other cells into areas of damaged muscle to clear away necrotic myofibers does not in any way constitute a form of myositis.

Because myonuclei are unable to divide, regeneration of muscle relies on satellite cell activation. Muscle satellite cells are resistant to many of the insults that result in myofiber necrosis, and activation of satellite cells is triggered by necrosis of adjacent myofiber segments. Therefore, as macrophages are clearing cytoplasmic debris, satellite cells are becoming activated and begin to divide in preparation for regeneration of the affected myofiber segment. If the myofiber basal lamina is still intact, it will leave an empty cylindrical space known as a “sarcolemmal tube.” This name is clearly a misnomer, dating from the days when the term “sarcolemma” was applied to the tube formed by the basal lamina that remains after segmental myofiber necrosis. Clearly what is now termed the sarcolemma (plasmalemma) of necrotic fiber segments is lost, but this is a misnomer that is firmly entrenched. The important concept to remember is that, if intact, the basal lamina will form a cylindrical scaffold to guide proliferating myoblasts and to keep fibroblasts out. Satellite cells may be seen undergoing mitosis, at which stage they are known as activated myoblasts, on the inner surface of this tube (Fig. 15-18, A). Within hours, proliferating myoblasts will fuse end-to-end to form myotubes (Fig. 15-18, B and C), and within days the myotube will produce thick and thin filaments and undergo maturation to a myofiber and will reestablish myofiber integrity. If the basal lamina is ruptured, myotubes are said to be able to bridge gaps of 2 to 4 mm, but any larger ones heal by fibrosis (see later discussion). The process of myofiber regeneration recapitulates embryologic development of skeletal muscle and is depicted schematically in Fig. 15-19. A percentage of dividing satellite cells will not fuse with the forming myotube, but will instead become new satellite cells capable of future regeneration.

986

987

**Fig. 15-18 Segmental necrosis and regeneration.** **A**, Monophasic segmental coagulation necrosis, skeletal muscle, longitudinal section of two myofibers. A segment of the upper fiber (*right*) and all the visible portion of the lower fiber have undergone necrosis, and macrophages have invaded through the intact basal lamina and cleared the cytoplasmic debris. Satellite cells on the inner surface of the basal lamina of the lower fiber are activated, and one (*lower left side*) is in mitosis. One  $\mu\text{m}$  plastic-embedded section, H&E stain. **B**, Polyphasic injury, segmental coagulation necrosis and regeneration of myofibers, muscle, longitudinal section. Between each of the foci of coagulation necrosis in the lowest myofiber is a segment of small-diameter faintly basophilic cytoplasm lacking cross striations, in which there is an internal chain of euchromatic nuclei. This is a late stage of regeneration. Formalin fixation, H&E stain. **C**, Monophasic injury, late stage regeneration, skeletal muscle, longitudinal section. The regenerating segment of the myofiber consists of myotubes, which have small diameters, with slightly basophilic cytoplasm and internal rows of large euchromatic nuclei. Formalin fixation, H&E stain. (**A**, Courtesy Dr. A. Kelly, University of Pennsylvania. **B**, Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University. **C**, Courtesy Dr. B.J. Cooper, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

In summary, the success of muscle regeneration depends on (1) the presence of an intact basal lamina and (2) the availability of viable satellite cells. The stages of successful muscle regeneration are summarized in [Box 15-5](#).

Thus myofibers undergoing segmental necrosis in which the basal lamina is preserved, as in metabolic, nutritional, and toxic myopathies, will regenerate very successfully. However, when large areas of satellite cells are killed (e.g., by heat, intense inflammation, or infarction), the situation is very different. In this case, a return to normal is not possible, and healing is chiefly by fibrosis.

If the insult to the muscle is sufficient to disrupt the myofiber basal lamina but not enough to damage the satellite cells, regeneration attempts are ineffective. Because the basal lamina is not intact, there is no tube to guide the myoblasts proliferating from each end. Myoblast proliferation under these conditions results in formation of so-called muscle giant cells ([Fig. 15-20](#)). Thus the presence of muscle giant cells indicates that 987  
conditions for regeneration have not been optimal, and occurs following destructive lesions, such as those 988  
caused by trauma that transects myofibers, infarction, and intramuscular bacterial infection or injection of irritants. Muscle giant cells are often accompanied by fibrosis, which will unite the ends of the damaged myofibers. This also occurs in muscle damaged by invasive or metastatic sclerosing carcinomas. Cytokines released from damaged muscle fibers contribute to the signaling pathways that initiate macrophage 988  
infiltration and regeneration, but they also contribute to interstitial fibroblast activation. Collagen is 989  
inelastic, and thus large areas of fibrosis inevitably reduce the ability of the muscle to contract and to stretch. Fibrosis within locomotory muscles often results in obvious alteration of the gait.

**Fig. 15-19 Schematic diagram of segmental myofiber necrosis and regeneration.** **A**, Myofiber, longitudinal section. **B**, Segmental coagulation necrosis. **C**, The necrotic segment of the myofiber has become floccular and detached from the adjacent viable portion of the myofiber. The satellite cells are enlarging. **D**, The necrotic segment of the myofiber has been invaded by macrophages, and satellite cells are migrating to the center. The latter will develop into myoblasts. The plasmalemma of the necrotic segment has disappeared. **E**, Myoblasts have formed a myotube, which has produced sarcoplasm. This extends out to meet the viable ends of the myofiber. The integrity of the myofiber is maintained by the sarcolemmal tube formed by the basal lamina and endomysium. **F**, Regenerating myofiber. There is a reduction in myofiber diameter with central rowing of nuclei. There is early formation of sarcomeres (cross striations), and the plasmalemma has re-formed. Such fibers stain basophilically with H&E. (*A through F, Redrawn with permission from Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

15.1.5.1.1

### Box 15-5 Stages of Muscle Regeneration under Optimal Conditions

1. Muscle nuclei disappear from the necrotic segment and the sarcoplasm becomes hyalinized (eosinophilic, amorphous, and homogeneous) because of the loss of normal myofibrillar structure (Fig. 15-19, *B*). The necrotic portion may separate from the adjacent viable myofiber (Fig. 15-16, *B*, Fig. 15-18, *A* and *B*, Fig. 15-19, *C*).
2. Within 24 to 48 hours, monocytes emigrate from capillaries, become macrophages, and enter the necrotic portion of the myofiber (Fig. 15-17, *B*, Fig. 15-18, *A*, Fig. 15-19, *D*). Concurrently, the satellite cells, located between the basal lamina and the sarcolemma, begin to enlarge (Fig. 15-18, *A*, Fig. 15-19, *C* and *D*), become vesicular with prominent nucleoli, and then undergo mitosis to become myoblasts.
3. Myoblasts migrate from the periphery to the center of the sarcolemmal tube, among the macrophages (Fig. 15-19, *D*).
4. Macrophages lyse and phagocytose necrotic debris and form a clear space in the sarcolemmal tube, and the shape of the sarcolemmal tube is maintained by the basal lamina (Fig. 15-18, *A*).
5. Myoblasts fuse with one another to form myotubes, which are thin, elongated muscle cells with a row of central, closely spaced nuclei. Developing myotubes send out cytoplasmic processes in both directions within the sarcolemmal tube (Fig. 15-19, *E*). When the processes contact each other or a viable portion of the original muscle fiber, they fuse. The regenerating fiber is characterized by (1) basophilia as a result of increased RNA content, (2) internal nuclei, often in rows, that have differentiated to myonuclei, (3) a lack of striations, and (4) a smaller than normal diameter (Fig. 15-18, *B* and *C*, Fig. 15-19, *F*).
6. The fiber grows and differentiates. Its diameter increases, the sarcoplasm loses its basophilia, and longitudinal and cross striations appear, indicating the formation of sarcomeres.
7. In most species, within several days, the muscle nuclei of regenerating fibers move to their normal position at the periphery of the fiber, just under the sarcolemma.

**Fig. 15-20 Ineffectual regeneration.** Large, bizarre multinucleate muscle giant cells are indicative of regeneration in an area in which the myofiber's basal lamina has been damaged. Because the wall of the “myotube” of basal lamina is not intact, regenerating sarcoplasm exudes through the defect and in cross section this appears as a “muscle giant cell.” Formalin fixation, H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Because segmental necrosis and regeneration are such a common result of a wide variety of insults (e.g., overexertion, selenium deficiency, and toxic injury), a histologic diagnosis of “segmental necrosis” is often not helpful in determining the cause of the disease. Pathologic classification of lesions according to distribution (i.e., focal, multifocal, locally extensive, and diffuse) and duration (i.e., acute, subacute, chronic) has proven to be extremely useful in determining the possible causes of segmental muscle necrosis. Pathologic classification of degenerative myopathies has been further enhanced by Dr. Byron Kakulas, who introduced the terms *monophasic necrosis* and *polyphasic necrosis*. Monophasic lesions are of the same duration, indicative of a single insult. Polyphasic lesions indicate an ongoing degenerative process. Thus a focal monophasic lesion could be the result of a single traumatic incident, such as an intramuscular injection (Fig. 15-11, B). A multifocal monophasic lesion could represent a single episode of overly strenuous exercise (exertional myopathy) or a toxin being fed on one occasion (e.g., a horse eating one dose of monensin; Figs. 15-16, B and Fig. 15-38, B). However, if the insult is repeated or ongoing, such as occurs in muscular dystrophy (Fig. 15-49), selenium deficiency, or continuous feeding of a toxin, then new lesions (segmental necrosis) will form at the same time that regeneration is taking place; in other words, it will be a multifocal and polyphasic disease (Fig. 15-18, B). Using this approach, it is sometimes possible to rule out a diagnosis (e.g., muscular dystrophy and selenium deficiency myopathy are typically

## Pathologic Basis of Veterinary Disease, 4th Edition

polyphasic), but this is not an invariable rule. For example, in livestock with borderline concentrations of selenium, a sudden stress can cause a monophasic necrosis.

The term “rhabdomyolysis” is often encountered, particularly in the clinical arena, and especially in association with exercise-induced muscle injury (exertional rhabdomyolysis) in human beings, horses, and dogs. Technically, *rhabdomyolysis* simply means necrosis (lysis) of striated muscle. This term was coined years ago to replace the term *myoglobinuria* as a description for the clinical entity of severe muscle injury associated with myoglobin release causing dark red discoloration of the urine. Thus rhabdomyolysis generally indicates the presence of a severe degenerative myopathy with a large degree of myofiber necrosis (Fig. 15-40). In horses, the term *exertional rhabdomyolysis* has become firmly entrenched as a clinical entity in which exercise-induced muscle injury is the presenting sign. The term *recurrent exertional rhabdomyolysis* is often employed in cases in which repeated bouts of exercise-induced muscle damage have been documented.

### 15.1.5.2 ALTERATION IN MYOFIBER SIZE

The normal myofiber diameter will vary depending on fiber type, the muscle examined, the species, and the age of the animal. In some species (e.g., horse, cat, and human beings), there are three distinct populations based on diameter: Type 1 fibers are the smallest, type 2B fibers the largest, and type 2A fibers are intermediate in size. Differing diameters in part reflect the oxidative needs of the fibers; oxygen diffuses more readily into the interior of small-diameter fibers. In the dog, all fiber types are oxidative, and fiber-type diameter is much more uniform. A histogram generated from morphometric analysis of fiber diameters will reveal the characteristics of individual muscles in various species. Not surprisingly, this type of detailed information is more readily available for human patients than for animals. Even without morphometric analysis, however, a pathologist experienced in examination of muscle can often determine whether there is a normal fiber-size distribution (based on fiber diameter in transverse section), or whether there is an increase in fiber-size variation. The finding of increased fiber-size variation suggests that something is wrong but in itself does not give any indication of cause. Increased fiber-size variation can be a result of fiber atrophy, fiber hypertrophy, or both, and is considered part of the spectrum of changes included in the term “chronic myopathic change” (Box 15-6).

Fibrosis  
Fat infiltration

#### 15.1.5.2.2 Atrophy

The term “atrophy” is used to imply either a reduction in the volume of the muscle as a whole or in the diameter of a myofiber. In the early stages of atrophy, it may be difficult or impossible to detect loss of

## Pathologic Basis of Veterinary Disease, 4th Edition

---

muscle mass by gross observation, and morphometric evaluation of myofiber diameters may be required. Several cellular physiologic processes can be activated to result in muscle atrophy. These include induction of lysosomal action to result in autophagy of cytoplasmic components, apoptosis (programmed cell death), and activation of the cytoplasmic ubiquitin-proteasomal machinery. Lysosomal activation is prominent in denervation atrophy and is the basis for the positive reaction of denervated fibers in alkaline phosphatase and nonspecific esterase preparations. The causes of muscle fiber atrophy include physiologic and metabolic processes, and denervation. In most instances, muscle atrophy is reversible provided the cause is corrected. The type of fiber undergoing atrophy varies depending on the cause, therefore fiber typing is often required for a definitive diagnosis. Interestingly, type 2 fibers are the most likely to atrophy under a variety of circumstances ([Box 15-7](#)).

### 15.1.5.2.2.1

#### Physiologic muscle atrophy

Decrease in myofiber diameter, and therefore in the overall muscle mass, is a physiologic response to lack of use (disuse atrophy), cachexia, and aging. Type 2 fibers are preferentially affected ([Fig. 15-21](#)). Disuse atrophy occurs relatively slowly, and only in muscles not undergoing normal contraction, such as that caused by severe lameness or in muscles of a limb that is splinted or enclosed in a cast. The degree of disuse atrophy will be variable but typically is not as severe as the atrophy of cachexia or denervation (see later discussion). Disuse atrophy is often asymmetric. Muscle atrophy due to cachexia can be profound, especially in cases of cancer cachexia in which increased circulating levels of tumor necrosis factor alter the muscle metabolism, favoring catabolic processes rather than anabolic processes. Cachexia also develops relatively slowly, and causes symmetric muscle atrophy. Muscle atrophy due to aging can be considered a milder form of cachexia. Starvation, malnutrition, and chronic renal and cardiac diseases can also result in cachexia.

### 15.1.5.2.2.1.1

#### Box 15-7 Fiber Types and Muscle Atrophy

1. Denervation: Type 1 and type 2 fibers; reinnervation leads to altered fiber-type patterns (fiber-type grouping)
2. Disuse: Predominantly type 2 fibers; may vary depending on the species and cause
3. Endocrine disease: Predominantly type 2 fibers; associated with hypothyroidism and hypercortisolism
4. Malnutrition, cachexia, and senility: Predominantly type 2 fibers
5. Congenital myopathy: Often predominantly type 1 fibers

Fig. 15-21 **Disuse atrophy, dog.** **A**, Transverse section of normal biceps femoris muscle. **B**, Same muscle, same magnification, 60 days after disuse. Both type 1 (*light*) and type 2 (*dark*) fibers are atrophic, but type 2 fibers are more severely affected. Frozen section, ATPase pH 9.8. (**A and B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

### 15.1.5.2.2.2

#### Atrophy due to endocrine disease

Preferential atrophy of type 2 fibers causing symmetric muscle atrophy also occurs because of various endocrine disorders. The most common are hypothyroidism and hypercortisolism in dogs. Aging horses with pituitary dysfunction or tumors (leading to equine Cushing's syndrome) often develop muscle atrophy, presumably predominantly of type 2 fibers. The exact mechanisms by which these disorders cause myofiber atrophy are not clear, but myofibers contain a high concentration of surface receptors for several hormones. Atrophy due to endocrine disease likely reflects the intimate interrelationship between the endocrine and the muscular systems.

990

991

### 15.1.5.2.2.3

#### Denervation atrophy

This atrophy, also known by the misnomer “neurogenic atrophy,” is not uncommon in veterinary medicine. Maintenance of normal myofiber diameter is dependent on trophic factors generated by an intact associated nerve. Loss of neural input results in rapid muscle atrophy, and more than half the muscle mass of a completely denervated muscle can be lost in a few weeks. This trophic effect is not dependent on contractile activity because denervation atrophy is not a feature of neuromuscular junction disorders such as botulism and myasthenia gravis. In these disorders, there is a failure of neuromuscular transmission, but the nerve to the muscle is intact; therefore the muscle is technically still innervated. Generalized neuropathies or neuronopathies, such as equine motor neuron disease, will result in widespread and symmetric muscle atrophy. More commonly, however, only select nerve

## Pathologic Basis of Veterinary Disease, 4th Edition

damage is present, resulting in asymmetric muscle atrophy. One example is equine laryngeal hemiplegia (roaring) secondary to damage to the left recurrent laryngeal nerve ([Fig. 15-22](#)). It should be pointed out that purely demyelinating disorders of peripheral nerves can cause profound neuromuscular dysfunction, but axons are still intact. Associated myofibers are not technically denervated and therefore do not undergo denervation atrophy.

**Fig. 15-22 Denervation muscle atrophy, left cricoarytenoideus dorsalis muscle, larynx, dorsal surface, horse.** Note the unilateral (*left side*) atrophy and pale gray to white discoloration of the muscle. This horse had a peripheral neuropathy, which had led to laryngeal hemiplegia. (*Courtesy College of Veterinary Medicine, University of Illinois.*)

Following denervation, fibers become progressively smaller in diameter as peripheral myofibrils disintegrate. If an atrophic fiber is surrounded by normal fibers, it will be pressed into an angular shape, called an angular atrophied fiber. The angular atrophied fibers of denervation atrophy most often occur either singly or in small contiguous groups (small group atrophy) ([Fig. 15-23, A](#)). In more severe denervating conditions, in which many fibers within muscle fascicles are undergoing denervation atrophy, there are no normal fibers to cause compression and angularity, and affected fibers occur as larger groups of small diameter rounded fibers (large group atrophy; [Fig. 15-23, B](#)). Although myofibrils disappear rapidly, muscle nuclei do not do so at the same rate, and therefore

991

992

## Pathologic Basis of Veterinary Disease, 4th Edition

denervation atrophy is often associated with a notably increased concentration of myonuclei. The breakdown of glycogen in the myofiber is an early change in denervation atrophy, and therefore denervated fibers stain faintly, or not at all, with the PAS reaction.

**Fig. 15-23 Denervation atrophy, transverse sections.** Both sections are from horses with equine motor neuron disease. **A**, In relatively mild denervation, severely atrophied and angular fibers form small contiguous clusters indicative of small group atrophy. Formalin fixation, Masson trichrome stain. **B**, In severe denervation, entire fascicles of fibers undergo rounded atrophy characteristic of large group atrophy (*lower left*). Small group atrophy and admixed fiber hypertrophy are also present. A single pale stained fiber (*arrow*) is undergoing acute necrosis. There is also mild endomysial and perimysial fibrosis and mild fat infiltration (*empty vacuoles in the upper right and lower left*). Frozen section, modified Gomori's trichrome stain. (*A and B, Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

A histologic diagnosis of denervation atrophy may be suspected, based on the characteristic features of routinely processed muscles, but is most reliably documented with histochemistry or immunohistochemistry to detect fiber types. The loss of a nerve fiber to a muscle results in atrophy of all myofibers innervated by that nerve. Because of the intermingling of motor units forming a mosaic pattern of fiber types, myofibers undergoing denervation atrophy are scattered in a section of muscle. Because the motor neuron determines the histochemical myofiber type, and because denervating diseases typically involve both type 1 and type 2 neurons or nerves, atrophy of both type 1 and type 2 myofibers in muscle fasciculi is the hallmark of denervation atrophy (Fig. 15-24, A).

In denervation atrophy, histologic examination of the intramuscular nerves is warranted because it may reveal axonal degeneration or loss of myelinated fibers. Masson trichrome stain can be useful here because it will differentiate myelin (red) from collagen (blue). If the nerve damage does not incapacitate the animal and the muscle can still be used (e.g., in locomotion), the remaining innervated myofibers often undergo notable hypertrophy because of increased workload. Often the hypertrophied fibers in chronic denervation are type 1. Even without fiber typing, a pattern of severe small or large group atrophy (Fig. 15-23, A), especially if associated with notable fiber hypertrophy (Fig. 15-23, B), is strongly suggestive of denervation atrophy. A finding of associated peripheral nerve damage will be definitive.

Under many circumstances, denervated muscle fibers can be reinnervated by subterminal sprouting of axons from adjacent normal nerves. Reinnervation results in return to normal myofiber diameter, but reinnervation will often be from sprouts of a different type of nerve. Because muscle fiber type is a function of the motor neuron, the newly innervated myofiber will take on the fiber type determined by that neuron. This process results in a loss of the normal arrangement of type 1 and 2 myofibers and the formation of groups of the same fiber type adjacent to each other, called fiber-type grouping (Fig. 15-24). Thus fiber-type grouping is the hallmark of denervation followed by reinnervation. What appears to be fiber-type grouping can also occur because of fiber-type conversion (most often to type 1 fibers) in chronic myopathic conditions. Careful evaluation of the peripheral nervous system structure and function will help to distinguish neuropathic from myopathic changes. If previously reinnervated fibers are denervated again, the pattern will include large groups of atrophied fibers of a single fiber type, a process known as type-specific group atrophy. Type-specific group atrophy is far less common in animals than in human beings. Fiber-type grouping and type-specific group atrophy can only be detected by methods that distinguish fiber types. Changes occurring as a result of denervation and reinnervation are illustrated in Fig. 15-25.

992

993

**Fig. 15-24 Denervation atrophy and reinnervation, skeletal muscle, transverse sections.** **A**, Fiber typing reveals angular atrophy of both type 1 (*light*) and type 2 (*dark*) fibers, characteristic of denervation atrophy. In this case, there is also a loss of the normal mosaic pattern of fiber types, with groups of type 1 and of type 2 fibers indicative of reinnervation. This section is from a horse with laryngeal hemiplegia. Frozen section, ATPase pH 10.0. **B**, Fiber-type grouping in a dog indicative of denervation and reinnervation secondary to corticosteroid therapy. There is a loss of the normal mosaic pattern of fiber types, with grouping of type 1 (*light*) and type 2 (*dark*) fibers. The lack of angular atrophied fibers indicates that active denervation is not occurring at this time. Frozen section, ATPase pH 9.8. (**A**, Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University. **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 15-25 Schematic diagram of motor units undergoing denervation and reinnervation.** **A**, Terminal axon branches innervate multiple myofibers, and myofiber type is determined by the electrical activity of the type of neuron innervating the myofiber. Normally the terminal axons of the motor units are intermingled, with the result that the differently stained myofiber types form a mosaic pattern. **B**, If a neuron (or axon) is damaged, the axon will undergo Wallerian degeneration, and the myofibers in that motor unit will undergo denervation atrophy. Small group atrophy is illustrated here. **C**, Axonal sprouts from a healthy neuron can reinnervate affected fibers and cause restoration of their normal diameter. The myofibers will assume the fiber type of the new motor unit, which often causes fiber-type conversion, leading to fiber-type grouping. **D**, If neuronal (or axonal) damage is progressive, denervation atrophy of large groups of fibers of a single type can occur, known as type-specific group atrophy. This type of atrophy is less common in animals than in human beings. (*A through D, Redrawn with permission from Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

15.1.5.2.2.4

### Atrophy due to congenital myopathy

Congenital myopathy in children is often associated with selective type 1 fiber atrophy. This finding is less common in congenital myopathies identified thus far in animals. Selective type 1 atrophy is, however, a feature of feline nemaline myopathy, an animal model of congenital nemaline myopathy in children.

**Fig. 15-26 Fiber type splitting of hypertrophied myofibers, nemaline myopathy, skeletal muscle, transverse section, cat.**

Sarcolemmal ingrowth into the myofiber has resulted in multiple partitions with the formation of four myofibers; however, all myofibers are enclosed by one basal lamina. Frozen section, modified Gomori's trichrome stain. (Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.)

15.1.5.2.3

### Hypertrophy

Myofibers are increased in diameter by the addition of myofilaments. Physiologic hypertrophy is the normal process of myofiber enlargement that occurs with exercise conditioning. Compensatory hypertrophy occurs because of pathologic conditions that (1) decrease the number of functional myofibers or (2) interfere with normal cellular metabolic or other physiologic processes. Compensatory myofiber hypertrophy is therefore considered a relatively nonspecific response to a variety of insults. Fibers undergoing compensatory hypertrophy can enlarge to more than 100  $\mu\text{m}$  in diameter (normal is less than approximately 60 to 70  $\mu\text{m}$ ). Fiber hypertrophy often accompanies fiber atrophy, which contributes to increased fiber-size variation in various myopathic and neuropathic conditions.

Compensatory hypertrophy can occur because of a decrease in the number of functional myofibers. Thus, in a partially denervated muscle, the remaining innervated fibers hypertrophy (Fig. 15-23, B),

## Pathologic Basis of Veterinary Disease, 4th Edition

---

presumably as a result of increased workload. Pathologically hypertrophied fibers will have less oxygen diffusion from interstitial capillaries to internal portions of the myofiber, which can lead to myofiber damage. Mechanical overloading of hypertrophied muscle fibers is also possible. Overloading of hypertrophied fibers can result in segmental necrosis (Fig. 15-23, *B*), or fibers can undergo longitudinal fiber splitting to generate one or more smaller-diameter fragments, all contained within the same basal lamina (Fig. 15-26). Serial sections of areas of fiber splitting generally reveals that splits do not extend the entire length of the myofiber. Fiber splitting is considered a form of cytoarchitectural alteration (see later discussion).

993

994

### 15.1.5.3 CYTOARCHITECTURAL CHANGES

In addition to fiber splitting, a variety of other cytoarchitectural changes can occur within myofibers. Some are degenerative, reflecting an insult that is damaging to the myofiber but that does not culminate in necrosis. Others reflect underlying ultrastructural alterations that may be either pathologic or compensatory in nature. The functional significance of many of the myofiber cytoarchitectural changes is not known.

#### 15.1.5.3.1 Vacuolar Change

Vacuolar change is a common cytoplasmic alteration. In routinely processed muscle samples, or in any sample subjected to less than ideal handling, true vacuolar change can be very difficult to distinguish from artifact. Vacuoles can be an early manifestation of processes leading to necrosis, they can reflect underlying sarcotubular dilation, as occurs in many myotonic conditions (see later discussion), they can be caused by abnormal storage of carbohydrate or lipid, or they can reflect underlying myofibrillar abnormalities. Additional studies are often necessary to determine the cause of vacuolar change. When severe, such as in glycogen storage diseases, the term “vacuolar myopathy” is often employed.

#### 15.1.5.3.2 Internal Nuclei

Myonuclei of mature myofibers are found peripherally, just below the sarcolemma. Nuclei located one nuclear diameter or more from the sarcolemma are known as internal nuclei. (Note: The term “central nuclei” is considered incorrect because few abnormally placed nuclei are exactly centrally located.) Internal nuclei are rare in normal mammalian muscle, but a small percentage can be found normally in avian and reptilian species. Rows of internal nuclei in small-diameter, slightly basophilic myofibers are characteristic of the myotubular stage of regeneration (Fig. 15-18, *B and C*). In most species, peripheralization of myonuclei occurs early in regeneration, within days of myotube formation. Rodents are the exception. In rodents, internal nuclei are retained following regeneration, which provides a handy marker for fibers that have undergone necrosis and regeneration in studies using these species. In other mammalian species, the presence of internal nuclei in normal or hypertrophied fibers is a nonspecific finding indicative of chronic myopathic change (Fig. 15-27; Box 15-6). In hypertrophied fibers, the migration of myonuclei to the internal portion of the myofiber can precede the sarcolemmal infolding that creates fiber splitting.

**Fig. 15-27 Chronic myopathic change, medial triceps muscle, horse.**

The variation in myofiber diameter and the presence of one or more internal nuclei in most myofibers are indicative of a chronic myopathic change. Frozen section, H&E stain. (Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.)

### 15.1.5.3.3

#### Whorled and Ring Fibers

The cytoarchitectural rearrangements resulting in whorled and ring fibers are best appreciated on transverse sections. Whorled fibers contain spirals of cytoplasm with internally located nuclei. Whorled fibers can be seen in areas of chronic denervation, and also in areas in which myofiber necrosis with incomplete regeneration has occurred. Ring fibers (also known as “ringbinden”) contain a peripheral rim of sarcomeres oriented perpendicular to their normal orientation, resulting in peripheral radiating striations. Ring fibers are visible with many stains, both in frozen sections and in routinely processed sections. In either frozen or routine sections, they are best visualized in sections stained with PAS (Fig. 15-28, A). In human beings, ring fibers are common in a specific form of inherited muscular dystrophy known as myotonic dystrophy, but they are also seen in other myopathic and in neuropathic conditions and therefore are not specific for myotonic dystrophy. Similarly, there is no animal disorder in which ring fibers are specific, and these fibers can be seen in a variety of myopathic and neuropathic conditions. The presence of ring fibers can only be considered a chronic myopathic change. For example, in muscle studied from a horse with long-standing, non-weight-bearing foreleg lameness, numerous ring fibers were found in muscle from the weight-bearing limb.

### 15.1.5.3.4

#### Other Cytoarchitectural Changes

Many other cytoarchitectural changes reflect alterations in mitochondrial density or integrity and are best appreciated on examination of frozen sections, in which mitochondria can be visualized, or on ultrastructural examination. The presence of peripheral aggregates of mitochondria that stain red with

994

995

## Pathologic Basis of Veterinary Disease, 4th Edition

---

modified Gomori's trichrome stain form the basis of what are called “ragged red” fibers. Ragged red fibers are a hallmark of mitochondrial myopathy in human beings. In animals, however, ragged red fibers are common in various myopathic conditions, and fibers that would be considered to be ragged red fibers occur in normal dog and horse muscle. Mitochondrial abnormalities are also detected with oxidative enzyme reactions, such as NADH (Fig. 15-28, *B*) and SDH. Nemaline rods, formed by expansions of the Z-line material, stain purple to red with modified Gomori's trichrome stain on frozen sections. These rods can also be seen in animals with other myopathic conditions. Moth-eaten fibers contain multiple pale zones because of loss of mitochondrial oxidative enzyme activity on frozen sections, and occur in denervating disorders and in myopathic conditions (Fig. 15-28, *C*). Sarcoplasmic masses are pale-staining zones at the periphery of myofibers. These can be seen in routinely stained muscle sections. Ultrastructurally, they often contain disarrayed myofilaments with or without degenerate mitochondria. Other less commonly encountered alterations in animal muscle are pale central cores visible with mitochondrial stains, tubular aggregates composed of sarcotubular membranes, and target fibers in which mitochondrial oxidative enzyme reactions reveal central clear zones surrounded by a thin rim of highly reactive cytoplasm.

15.1.5.4

### CHRONIC MYOPATHIC CHANGE

Evaluation of abnormal skeletal muscle often reveals what is known as chronic myopathic change, which includes alterations in fiber size, cytoarchitectural alterations, fibrosis, and fat infiltration (Box 15-6). Chronic myopathic change will accompany a variety of myopathic and neuropathic conditions. In some cases, particularly severe cases, a definitive cause cannot be identified. Chronic inflammation or denervation and chronic degenerative myopathy resulting in repeated bouts of myonecrosis and regeneration often cause diffuse endomysial and perimysial fibrosis (Figs. 15-23, *B* and 15-52, *B*). Interstitial infiltration of muscle by mature adipocytes is less common than fibrosis and occurs most commonly in chronically denervated muscle (Fig. 15-23, *B*), particularly neonatal muscle that lacks appropriate innervation (Fig. 15-29). Fat infiltration can also occur because of severe chronic degenerative myopathy. A chronically damaged or denervated muscle that develops profound fibrosis and/or fat infiltration can be grossly enlarged despite atrophy or loss of myofibers—a condition known as pseudohypertrophy (Fig. 15-11, *D*).

**Fig. 15-28 Cytoarchitectural changes, skeletal muscle, transverse sections. A,** Ring fiber, extensor carpi radialis muscle, horse. A ring fiber is characterized by a peripheral rim of sarcomeres, arranged circumferentially around a myofiber and with their length at right angles to the long axis of the myofiber. Frozen section, PAS reaction. **B,** Irregular mitochondrial distribution with peripheral aggregates of mitochondria, Labrador myopathy, temporalis muscle, dog. Frozen section, NADH reaction. **C,** Irregularity of mitochondrial distribution and “moth-eaten” fibers, polyneuropathy, dog. Fibers containing pale zones are characteristic of moth-eaten fibers. Fig. 15-29 **Lipomatosis (steatosis), calf.** Lost myocytes have been replaced by mature adipocytes. Islands of remaining myofibers have groups of angular atrophied fibers admixed with hypertrophied fibers, suggestive of denervation atrophy. Formalin fixation, H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

### 15.2 DISEASES OF MUSCLE

#### 15.2.1 TYPES OF MUSCLE DISEASE

Classification of muscle diseases based on lesions alone is not very satisfactory, and many classifications are based on cause (e.g., toxic myopathy or nutritional myopathy). An example of such a classification is given in [Table 15-3](#). Myopathic conditions can be inherited or acquired. Inherited disorders can affect muscle metabolism or myofiber structure. Acquired muscle disease in livestock is often associated with nutritional deficiency or to ingestion of myotoxins, whereas acquired muscle disease in the dog is most often caused by immune-mediated inflammatory conditions. Other causes of acquired myopathies include ischemia, infectious agents, hormonal or electrolyte abnormalities, and trauma. There are also many neuropathic conditions that result in denervation atrophy (see peripheral nerve discussion). More information on most of the disorders described in this section can also be found under the appropriate species heading or in [Appendix 15-1](#).

##### 15.2.1.1 DEGENERATIVE

Degenerative myopathies are those resulting in segmental or global myofiber necrosis in which inflammatory cells are not the cause of the myofiber damage.

## Pathologic Basis of Veterinary Disease, 4th Edition

15.2.1.1.1

### Disturbance of Circulation

Given the numerous capillary anastomosis and rich collateral circulation of skeletal muscle, only disorders that result in occlusion of a major artery or that cause widespread intramuscular vascular damage will result in myofiber necrosis (Box 15-8). Vascular occlusion of a major artery, most often aortoiliac thrombosis, occurs most commonly in cats (thromboembolism) and horses (mural thrombosis). Intramuscular vascular damage occurs in many species, and there are a variety of causes.

Table 15-3 Classification of Muscle Disease

Classification	Cause or Type of Disorder
Degenerative	Ischemia Nutritional Toxic Exertional Traumatic
Inflammatory	Bacterial Viral Parasitic Immune-mediated
Congenital and/or inherited	Anatomic defects Muscular dystrophy Congenital myopathy Myotonia Metabolic Malignant hyperthermia
Endocrine	Hypothyroidism Hypercortisolism
Electrolyte	Hypokalemia Hypernatremia Other electrolyte imbalances
Neuropathic	Peripheral neuropathy Motor neuronopathy
Neuromuscular junction disorders	Myasthenia gravis Botulism Tick paralysis
Neoplasia	Primary tumors (rhabdomyoma, rhabdomyosarcoma) Secondary tumors (hemangiosarcoma, fibrosarcoma, infiltrative lipoma, other tumor phenotypes) Metastatic tumors

The basic factor in determining the effect of ischemia on muscle is the differential susceptibility of the various cells forming the muscle as a whole. Myofibers are the most sensitive, satellite cells less sensitive, and fibroblasts the least sensitive to anoxia. Thus obstruction of the blood supply to an area of muscle leads first to myofiber necrosis, then to death of satellite cells, and finally to the death of all cells, including the stromal cells. The size of skeletal muscle infarcts depends on the size of the vessel obstructed and the duration of blockage. Blockage of capillaries causes segmental necrosis, which is usually multifocal and, if the cause is ongoing, polyphasic. However, when larger arteries are blocked, whole areas of muscle, including the satellite cells, are killed, resulting in a monophasic necrosis and healing by fibrosis. Ischemia can also cause peripheral nerve damage and neuropathy, leading to denervation atrophy of intact fibers.

996

997

### Box 15-8 Causes of Muscle Ischemia

1. Occlusion of a major blood vessel
2. External pressure on a muscle
3. Swelling of a muscle in a nonexpandable compartment (“compartment syndrome”)
4. Vasculitis/vasculopathy

Increased intramuscular pressure can occur in a recumbent animal of sufficient weight after a prolonged period of recumbency, either because of disease or general anesthesia. Myofiber necrosis due to recumbency can occur because of (1) decreased blood flow as a result of compression of major arteries, (2) reperfusion injury causing massive calcium influx into muscle cells when the animal moves or is moved and the compression relieved, (3) increased intramuscular pressure causing compartment syndrome, or (4) any combination of these factors. Localized myonecrosis due to recumbency is common in horses, cattle, and pigs; occurs only in large breeds of dogs; and is virtually unheard of in cats. In downer cows, the weight of the body of the animal in sternal recumbency can cause ischemia of the pectoral muscles and of any muscles of the forelimbs or hindlimbs that are tucked under the body. Ewes in advanced pregnancy with twins or triplets can develop an ischemic necrosis of the internal abdominal oblique muscle, which can lead to muscle rupture. Plaster casts or bandages that are too tight can put external pressure on muscles, leading to ischemia. The duration of ischemia determines the severity of necrosis and the success of regeneration (see Necrosis and Regeneration). Postanesthetic myopathy is a monophasic, multifocal necrosis. In the downer cow, the lesions are multifocal to locally extensive ([Fig. 15-30](#)) and, depending on the duration, can be either monophasic or polyphasic.

Any severe insult, whether it be ischemia caused by recumbency or another myodegenerative disorder, that causes myonecrosis within a muscle that is covered by a tight and nonexpansile fascia can result in ischemic injury because early in the necrosis there is increased intramuscular pressure. The resulting compromise of blood circulation leads to ischemic myodegeneration, known as compartment syndrome. The phenomenon of compartment syndrome is best illustrated in the anterior tibial muscle of human beings following strenuous exercise. This condition is believed to be a consequence of swelling of the anterior tibial muscle, which is surrounded anteriorly by the inelastic anterior fascial sheath and posteriorly by the tibia. Swelling impedes blood supply, resulting in ischemia. A similar phenomenon occurs in muscles surrounded by tight fascia in animals, particularly horses. Horses that are recumbent because of general anesthesia can develop compartment syndrome affecting gluteal or lateral triceps muscles. Horses can also develop compartment syndrome in gluteal muscles because of exertional rhabdomyolysis, and in temporal and masseter muscles because of selenium deficiency. Compartment syndrome is also possible in the temporal and masseter muscles of dogs with masticatory myositis.

**Fig. 15-30 Ischemic necrosis, downer cow syndrome, pectoral muscle, cow.** Increased intramuscular pressure during prolonged periods of recumbency has resulted in localized muscle pallor from myofiber necrosis secondary to decreased blood flow caused by compression of arteries. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Damage to intramuscular blood vessels will also cause myofiber necrosis. Vasculitis can cause areas of muscle damage (e.g., in horses with immune-mediated purpura hemorrhagica because of *Streptococcus equi* infection [Fig. 15-37] and in pigs with erysipelas). Viral diseases that target blood vessels of many organs, such as bluetongue, can also affect muscle. Exotoxins produced by clostridial organisms cause myositis and severe localized vascular damage, leading to hemorrhage and myofiber necrosis (Table 15-4). The familial myopathy of Gelbvieh cattle is characterized by fibrinoid necrosis of intramuscular blood vessels and associated myonecrosis.

### 15.2.1.1.2

#### Nutritional Deficiency

Myofibers are particularly sensitive to nutritional deficiencies that result in loss of antioxidant defense mechanisms. Nutritional myopathies are most common in livestock, including cattle, horses, sheep, and goats (Table 15-5). Although nutritional myopathy of livestock is often referred to as selenium/vitamin E deficiency, in the vast majority of cases it is deficiency of selenium that is the cause of myofiber degeneration. The trace mineral selenium is a vital component of the glutathione peroxidase system,

997

998

## Pathologic Basis of Veterinary Disease, 4th Edition

which helps to protect cells from oxidative injury. The high oxygen requirement combined with contractile activity makes striated muscle, both skeletal and cardiac, particularly sensitive to oxidative injury. Neonatal animals, which rely on stores of selenium accumulated during gestation, are most often affected. Affected muscle is pale as a result of necrosis (Fig. 15-44); hence the common name white muscle disease. As should be evident from the previous discussion, a gross observation of pale muscle is not specific for necrosis caused by nutritional deficiency; therefore the term nutritional myopathy is much preferred.

Table 15-4 Clostridial Toxins Causing Muscle Damage

Toxin	Type	Action
$\alpha$ -Toxin	Calcium-dependent phospholipase	Hydrolyzes membrane phospholipids
$\theta$ -Toxin	Oxygen-labile cytotoxin (perfringolysin-O)	RBC and WBC lysis
		Induces platelet-activating factor leading to leukostasis and decreased tissue perfusion
$\kappa$ -Toxin	Collagenase	Contributes to tissue lysis
$\mu$ -Toxin, $\gamma$ -toxin	Hyaluronidases	Disruption of muscle integrity
$\epsilon$ -Toxin	Lipase	Lipid membrane lysis

RBC, Red blood cell; WBC, white blood cell.

15.2.1.1.3

### Toxic Myopathies

Here again, livestock are the animals most prone to develop a degenerative myopathy from the ingestion of a toxin (Table 15-5). Myotoxins can be present in plants in pastures or hay, and in plants or plant products in processed feed. Examples of toxic plants and plant products include *Cassia* (coffee senna), *Karwinskia* (coyotillo), *Eupatorium* (white snakeroot), *Thermopsis* spp., and gossypol present in cottonseed. Clinical signs are weakness, often leading to recumbency, and are accompanied by a moderate to severe increase in serum muscle enzyme concentrations. Gross and histologic findings of multifocal necrosis that can be either monophasic or polyphasic are typical. Diagnosis is based on identification of causative plants within feed, pasture, or stomach contents or, when available, detection of toxic compounds in stomach content or liver.

Table 15-5 Nutritional and Toxic Myopathies

Disorder	Species Affected	Cause
Nutritional myopathy	Horses, cattle, sheep, goats, camelids, pigs	Selenium or (less commonly) vitamin E deficiency
Ionophore toxicity	Horses, cattle, sheep, goats, pigs	Monensin, other ionophores used as feed additives
Plant toxicity	Horses, cattle, sheep, goats, pigs	<i>Cassia occidentalis</i> , other toxic plants; gossypol in cottonseed products
Pasture-associated myopathy (United Kingdom)	Horses	Unknown

Ionophore antibiotics such as monensin, lasalocid, maduramicin, and narasin are often added to ruminant feeds to enhance growth. Ionophores form lipid soluble dipolar reversible complexes with cations and allow movement of cations across cell membranes, often against the concentration gradient. This causes a disruption of ionic equilibrium that can be detrimental, especially to excitable tissue such as the nervous system, heart, and skeletal muscle. Ionophore toxicity results in calcium overload and death of skeletal (Figs. 15-16, B and 15-38) and cardiac muscle. Most domestic ruminants are quite tolerant of

## Pathologic Basis of Veterinary Disease, 4th Edition

---

moderate ionophore levels, but toxicity occurs at very high levels. Most cases of ionophore toxicity involve monensin. The LD<sub>50</sub> (the dose at which 50% of animals die) of monensin in cattle is 50 to 80 mg/kg and for sheep and goats is 12 to 24 mg/kg. Horses are exquisitely sensitive to ionophores and even very low levels are toxic, with an LD<sub>50</sub> for monensin of only 2 to 3 mg/kg of body weight.

15.2.1.1.4

### Exertional Myopathies

The ionic and physical events associated with myofiber contraction can, under certain circumstances, predispose a myofiber to necrosis. Exercise-induced myonecrosis, which can be massive, can occur because of simple overexertion. This outcome is well known in the capture and restraint of nondomesticated species, a syndrome known as capture myopathy. More often, however, exercise-induced myofiber damage occurs in animals with preexisting conditions such as selenium deficiency, muscular dystrophy, severe electrolyte depletion, or glycogen storage disease. The term “exertional rhabdomyolysis” (also known as exertional myopathy, azoturia, setfast, blackwater, Monday morning disease, and tying up) has long been applied to a syndrome recognized in horses (Fig. 15-40). Only recently have underlying myopathic conditions been identified as the most common predisposing cause of equine exertional rhabdomyolysis (see Muscular Disorders of the Horse). A similar disorder affects working dogs, such as racing sled dogs and greyhounds, the cause of which is still unclear.

15.2.1.1.5

### Trauma

External trauma to muscle includes crush injury, lacerations and surgical incisions, tearing due to excessive stretching or exercise, burns, gunshot and arrow wounds, and certain injections. Some of these result in complete or partial rupture of large muscles. The diaphragm is the most common muscle to rupture and in dogs and cats is most often due to sudden increase in intraabdominal pressure, such as from being hit by a car. In horses, diaphragmatic rupture is thought to occur most often during falls in which the pressure of the abdominal viscera causes diaphragmatic damage. A partial rupture of a muscle results in a tear in the fascial sheath, through which the muscle can herniate during contraction. In racing greyhounds, spontaneous rupture of muscles, such as the longissimus, quadriceps, biceps femoris, gracilis, triceps brachii, and gastrocnemius can occur during strenuous exercise. In horses, damage to the origin of the gastrocnemius muscle has been linked to overexertion during exercise or while struggling to rise. Tearing of muscle fibers occurs in the adductor muscles of cattle doing the “splits” on a slippery floor. Because there is often extensive disruption of the myofibers' basal laminae, most of the healing is accomplished by fibrosis. If muscle trauma is accompanied by fractures of bones, and the animal moves the limb, this can result in further trauma because of laceration by sharp bone fragments.

An abnormal response to localized muscle trauma is thought to be a possible underlying cause of two uncommon reactions of muscle: myositis ossificans and musculoaponeurotic fibromatosis. The term *myositis ossificans* is a misnomer, as the lesion does not involve inflammation, but it has attained the status of acceptance by common usage. Myositis ossificans is a focal lesion usually confined to a single muscle and has been seen in horses, dogs, and human beings. The lesion is essentially a focal zone of fibrosis with osseous metaplasia, often with a zonal pattern. The central zone contains proliferating undifferentiated cells and fibroblasts; the middle one, osteoblast depositing osteoid and immature bone; and the outer one, trabecular bone, which may be being remodeled by osteoclasts. These lesions can cause pain and lameness but are often cured by surgical excision. A connective tissue disorder in cats, fibrodysplasia ossificans progressiva, has been inappropriately called myositis ossificans. Musculoaponeurotic fibromatosis has so far been described only in horses and human beings. It is a progressive intramuscular fibromatosis that has also been called a desmoid tumor. Musculoaponeurotic

## Pathologic Basis of Veterinary Disease, 4th Edition

fibromatosis is not, however, considered to be a true neoplastic process. Progressive dissecting intramuscular fibrosis accompanied by myofiber atrophy are the characteristic features. In most cases, the extent of intramuscular involvement makes surgical excision impossible, although wide excision of early lesions has proven to be curative.

### 15.2.1.2 INFLAMMATORY MYOPATHIES (MYOSITIS, MYOSITIDES [PLURAL])

In addition to the misnomer “myositis ossificans,” the term “myositis” has been inappropriately applied to various other veterinary disorders, such as exertional and nutritional myopathy in the horse. These two disorders are degenerative myopathies, not inflammatory myopathies. It is vitally important to distinguish between a true myositis and a degenerative myopathy in which there is a secondary inflammatory response. In the normal response to the necrosis, the necrotic segment is infiltrated by macrophages recruited from the circulating monocyte population (Figs. 15-17, *B* and 15-18, *A*), which phagocytose the cellular debris. Severe acute necrotizing myopathy can also be accompanied by a certain degree of infiltrating lymphocytes, plasma cells, neutrophils, and eosinophils. Cytokines released from damaged muscle fibers are likely to recruit a variety of inflammatory cells under various circumstances, but these cells are not involved in the muscle cell damage. True myositis occurs only when inflammatory cells are directly responsible for initiating and maintaining myofiber injury, and when inflammation is directed at the myofibers and not at the stroma. In some cases, it may take careful evaluation of the overall tissue changes, an understanding of the probable underlying cause, and years of experience with muscle pathology to distinguish a florid cellular response with macrophages on a “clean-up” mission from true inflammation. Lymphocytic myositis must also be distinguished from lymphoma involving skeletal muscle (see Neoplasia).

#### 15.2.1.2.1 Bacterial

Bacterial infections of muscle are not uncommon, particularly in livestock. Bacteria can cause suppurative and necrotizing, suppurative and fibrosing, hemorrhagic, or granulomatous lesions (Table 15-6). Bacterial infection can be introduced by direct penetration (wounds or injections), hematogenously, or by spread from an adjacent cellulitis, fasciitis, tendonitis, arthritis, or osteomyelitis (see Portals of Entry).

999

Table 15-6 Bacterial Myopathies

1000

Infectious Agent	Species Affected
<i>Clostridium</i> spp. causing myositis	Horses, cattle, sheep, goats, pigs
<i>Clostridium botulinum</i>	Horses, cattle, sheep, goats, dogs
Pyogenic bacteria	Horses, cattle, sheep, goats, pigs, cats
Agents causing fibrosing and granulomatous lesions	Cattle, sheep, goats, pigs
